possesses an SV40 replication origin that is stimulated by large-T antigen⁵ produced by the RβSVpBR328 co-transfected plasmid. The high copy number of α -globin genes obtained in transfected HeLa cell nuclei may effectively be in excess of the endogenous RNA polymerase II. Transcriptional interference effects would thus be diminished. However, endogenous chromosomal RNA polymerase II genes are usually single copy, so that RNA polymerase II should be in excess. Interference between adjacent genes could therefore be much higher. To test this possibility, I transfected $\alpha\alpha$ pSVod and α T α pSVod plasmids containing the neomycin drug resistance gene (neo)17 as part of the SV40 early gene transcription unit (Fig. 1a and legend) into HeLa cells. Following conditions for selection with the antibiotic G418, pools of resistant HeLa cell clones that had stably integrated the neo gene-containing plasmids were obtained, one pool for α T α pSVod and two separate pools for $\alpha\alpha$ pSVod. In each case, the complexity of each pool was in excess of 100 independent clones. Therefore, any specific chromosomal position effects on one clone should be averaged out. Similarly, clones in which integration of the plasmid occurred either between or within the two α genes should not influence the average levels of α -globin mRNA expression by the whole pool.

Figure 3 shows the primer extension data for RNA purified from the three G418-resistant HeLa cell pools. High amounts of RNA were used in the reverse transcriptase reactions because the level of α mRNA was lower than in the transient expression experiments. As indicated, both $\alpha\alpha$ pSVod pools gave a strong 5' α signal relative to the 3' α signal. Indeed, for $\alpha\alpha(1)$, which overall gave rather low α mRNA signals, no 3' α signal was detected at all, while for $\alpha\alpha(2)$, the 3' α signal was 20-fold lower than the 5' α signal. A third $\alpha\alpha$ pSVod pool has recently been analysed and shows 5-fold less $3'\alpha$ signal than $5'\alpha$ (data not shown). In contrast, with $\alpha T \alpha$ both 5' and 3' α signals were nearly equivalent. Note that a band (5') was routinely observed below the 3' α signal. Indeed, this band was more noticeable when using the high amounts of RNA necessary to detect α mRNA signal with the transfected HeLa cell pools. This band clearly derives from the 5' α signal, since no such band is visible with the α control lane but is detectable in the 5' α signal shown for $\alpha\Delta P\alpha$ in Fig. 1b. Presumably, this is due to the different RNA secondary structure of the Tag-containing α mRNA. Taken together, these data demonstrate a 5-to-20-fold level of transcriptional interference between the duplicated α genes when placed in a chromosomal environment. This interference can be wholly alleviated by placing the histone terminator between the two α genes.

The demonstration of a threefold interference effect between duplicated α genes in episomal plasmids and the greater, effect in chromosomes, clearly underlines the essential role of transcriptional terminators in eukaryotic gene transcription. Although in these experiments I have intentionally placed the two α genes in close proximity (~700 bp apart), it is probable that interference can occur over greater distances, especially since many gene transcription units are longer than 100 kb^{18,19}.

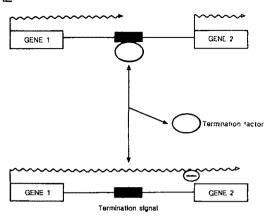

Fig. 4 Model for gene regulation by transcriptional interference.

The interesting possibility that the control of a gene could be partly mediated by transcriptional interference from an upstream gene is now a serious possibility. Figure 4 demonstrates a possible model for this type of control process. The model requires that a termination factor must recognize the termination signal to elicit transcriptional termination. Such an interaction would allow the downstream gene to operate free from upstream gene transcriptional interference. However, the absence or dissociation of the termination factor from the termination signal would allow upstream gene transcripts to read through the terminator to interfere with transcription of the downstream gene. So far, no such terminator factors have been identified for RNA polymerase II genes, although RNA polymerase I terminator factors have recently been identified²⁰. A possible variation on the model depicted in Fig. 4 could be that the factor recognizing the terminator sequence is an anti-termination factor, so that interference of the downstream gene would occur by anti-terminator factor binding rather than terminator factor release. Such terminator and anti-termination factors are well documented in prokaryotes, with the Escherichia coli termination factor rho and the bacteriophage λ N and Q antiterminators as classic examples²¹. It remains to be established whether or not equivalent termination factors are involved in the regulation of eukaryotic gene expression.

A number of my colleagues have contributed significantly to this project, Mike Johnson constructed the Tag α gene and did some preliminary experiments²³, Chris Norman constructed the H2A termination constructs, and Sarah Hargreaves carried out primer extension analysis on the $\alpha m \beta \alpha$ constructs. I also thank the members of my laboratory for many helpful discussions throughout these studies.

Cloning of a major surface-antigen gene of *Trypanosoma cruzi* and identification of a nonapeptide repeat

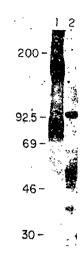

David S. Peterson, Ruth A. Wrightsman & Jerry E. Manning

Department of Molecular Biology and Biochemistry, University of California, Irvine, Irvine, California 92717, USA

The parasitic protozoan Trypanosoma cruzi can establish infection in humans and other vertebrate hosts through direct penetration of host cells by trypomastigotes transmitted by the insect vector¹. Although the molecular processes involved in trypomastigote interiorization of vertebrate cells are unknown, several studies suggest that surface glycoproteins are involved2-4. It is likely that the proteins involved are specific to the trypomastigote stage of the parasite, since only trypomastigotes found in both the insect vector and the vertebrate host bloodstream are capable of invading vertebrate cells. In contrast, the epimastigote stage, found exclusively in the vector, and the amastigote stage, an intracellular stage in the vertebrate host, cannot penetrate the cell directly. We have therefore concentrated our efforts on trypomastigote surface proteins and, along with others, have identified two trypomastigotespecific surface glycoproteins of relative molecular mass (M_r) 90,000 (90K) and 85,000 (85K)^{5,6}. Antibody neutralization experiments indicate that the 85K glycoprotein is necessary for efficient interiorization of trypomastigotes in mammalian cells. Here we describe the molecular cloning of a genomic DNA fragment that encodes antigenic determinants present in the 85K trypomastigote surface antigen. The polypeptide fragment encoded by the cloned DNA is recognized by serum from a T. cruzi-infected host and is inferred by DNA sequence analysis to contain a nonapeptide unit that is tandemly repeated five times. Also, the messenger complementary to the cloned DNA fragment is present only in the trypomastigote stage of the parasite.

We have previously reported that the major surface proteins of the trypomastigote stage can be isolated free of most cytosolic components by using iminobiotin-avidin interaction⁶. This preparation of iminobiotinylated surface proteins (IBSP) contains

Fig. 1 Immunoblot analysis of SDS-lysates of Peru strain trypomastigotes (lane 1) and Peru strain epimastigotes (lane 2) using anti-IBSP antibodies. Total cellular proteins were solubilized in Laemmli sample buffer¹⁵ at a concentration of 2×10^8 cells ml⁻¹. After being heated for 3 min, 25 µl of each lysate was added to each lane of a 10% polyacrylamide SDS gel. After electrophoresis the gel was electroblotted to nitrocellulose and processed as described previously⁶. The serum used to probe the filter was a 1:1,000 dilution of rabbit anti-IBSP serum. Detection of the rabbit antibody was with 125 Igoat-anti-rabbit IgG. Markers for calibration of the gel are ¹⁴C-methylated myosin (200,0000). phosphorylase-b (92,5000), bovine serum albumin (69,000), ovalbumin (46,000), carbonic anhydrase (30,000).

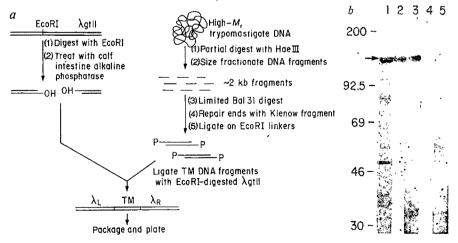

the major 85K and 90K glycoproteins as well as several minor surface polypeptides. Sera from rabbits immunized with the IBSP preparation recognized polypeptides of 90K, 85K and 76K in trypomastigotes, but not in epimastigotes, as determined by Western blot analysis (Fig. 1). In contrast, a 105K antigen was recognized in both forms of the parasite.

To obtain DNA fragments which encode a portion of the surface polypeptides, a recombinant DNA library was constructed in the expression vector λ gt11 (ref. 7) using fragments of Peru strain trypomastigote genomic DNA (Fig. 2a). Approximately 100,000 recombinant phage were screened with the anti-IBSP sera and 6 phage expressing T cruzi antigens were identified. One of these clones, Tcg-1, encoded a hybrid protein of M_r 132,000, which is approximately 16,000 daltons larger than β -galactosidase. In Western blots the fusion protein was recognized by the anti-IBSP sera as well as by sera from a mouse infected with T cruzi, thus indicating that the epitope(s) encoded in Tcg-1 is also recognized by the immune system of the infected host during an active T cruzi infection (Fig. 2b).

Since the anti-IBSP sera recognized several surface proteins, it was necessary to determine which surface protein was represented in the Tcg-1 fusion protein. BALB/c mice were immu-

Fig. 2 a, Construction and screening of a trypomastigote genomic DNA library. DNA of high Mr was isolated from culture-form trypomastigotes of the Peru strain, partially digested with endonuclease HaeIII, size fractionated by centrifugation on a 10-40% sucrose gradient and fragments with an average length of 2,000 bp were collected. After a 30 min digestion wih slow Bal31 nuclease, 5 µg DNA per unit of enzyme (International Biotechnologies Inc.), the resected DNA fragments were repaired with the Klenow fragment of Escherichia coli DNA polymerase I, and EcoRI linkers were added to the ends of the fragments to allow insertion into the single EcoRI site of λgt117. The recombinant molecules were packaged in vitro and plated on E. coli strain Y1090. Using 5-bromo-4-chloro-3-indolyl-α-D-galactopyranoside as an indicator, recombinant phage represented 85% of all plaques. Approxi-

mately 100,000 plaques were screened for antigen producers using a 1:500 dilution of rabbit anti-IBSP sera as described previously 16 except that 125 I-protein A was used to detect λ plaques recognized by the anti-IBSP sera. Six plaques produced positive signals upon successive rescreens with the anti-IBSP sera. b, Analysis and partial purification of the fused polypeptides encoded in Tcg-1. Tcg-1 hybrid protein and native β -galactosidase were partially purified as described by Hall et al. 18 . The proteins isolated from the induced lysogens were electrophoresed on a 10% polyacrylamide SDS gel at a concentration of 15 μ g protein per lane. After electrophoresis, lane 1 was stained with Coomassie blue and lanes 2-5 were electroblotted to nitrocellulose. In lane 1 the arrow denotes the position of the fusion protein at 132,000 M_r . Lanes 2 and 3 are Western blots of Tcg-1 fusion protein reacted with anti-IBSP sera (lane 2) and sera from a mouse infected with T cruzi (lane 3). Partially purified β -galactosidase from λ gt11 was Western blotted and reacted with anti-IBSP sera (lane 4) and T cruzi-infected mouse sera (lane 5).

Fig. 3 Identification of native proteins that share antigenic determinants with Tcg-1 fusion protein. Western blots of a trypomastigote lysate (lane 2) and epimastigote lysate (lane 3). Lane 1 shows a Western blot of a trypomastigote lysate probed with anti-IBSP sera at a 1:1000 dilution, Methods. Tcg-1 fusion protein (270 µg) was electrophoresed on a preparative 10% polyacrylamide SDS gel and electroblotted to nitrocellulose. Two strips of the extreme ends of the nitrocellulose blot were removed and probed with anti-IBSP sera to determine the precise location of the Tcg-1 fusion protein. The region of the nitrocellulose containing the fusion protein was excised and reacted with 5 ml of undiluted anti-IBSP sera plus 5 ml of blocking buffer as described previously8. After 10 washes in buffer containing 10 mM Tris pH 7.4, 0.9% saline, 0.05% Tween-20 and 0.01% gelatin, the bound antibody was eluted by incubation in 1.0 ml of 0.1 M glycine-HCl pH 2.6, 0.15 M NaCl and

immediately neutralized by addition of an equal volume of 1 M Tris-HCl pH 8.0. This antibody solution was used to probe the Western blots.

nized with a protein fraction enriched for Tcg-1 fusion protein. The mouse anti-Tcg-1 sera were absorbed against induced \(\lambda\) gt11 lysogens and used to probe lysates of trypomastigotes and epimastigotes on Western blots (not shown). While no polypeptides in the epimastigote lysate were recognized by the serum antibodies, two polypeptides of M_r 85,000 and 76,000 were recognized in the trypomastigote lysate. However, the intensities of the bands in the autoradiogram were weak, suggesting that a strong immune response was not elicited against the fusion protein. We used antibody selection⁸ to confirm the identity of the T. cruzi polypeptide encoded in Tcg-1. Tcg-1 fusion protein bound to nitrocellulose was used to affinity-purity antibodies from rabbit anti-IBSP sera. The affinity-purified antibodies recognized two polypeptides of 85K and 76K in Western blots of a trypomastigote lysate (Fig. 3). However, no polypeptides were detected in Western blots of epimastigote lysates. In a control experiment using native β -galactosidase under the same conditions as for antibody selection with Tcg-1 fusion protein, no polypeptides in either of the T. cruzi lysates were recognized. We conclude from these results that Tcg-1 contains DNA sequences that encode an epitope(s) present in the 85K and 76K polypeptides.

As shown in Fig. 1, both the 85K and 76K polypeptides are

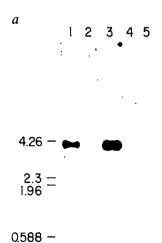

present in the trypomastigote but not epimastigote stage of the parasite. To determine whether the mRNA(s) which code for these polypeptides are also stage specific, the 500-base-pair (bp) T. cruzi DNA fragment in Tcg-1 was hybridized to a Northern blot containing poly(A)⁺ RNA and/or total cytoplasmic RNA extracted from trypomastigotes, epimastigotes and amastigotes. Hybridization was observed to a single mRNA band with an apparent molecular length of 3.8 kilobases (kb) only in trypomastigote RNA, thus confirming the stage specificity of these polypeptides (Fig. 4a).

The T. cruzi fragment in Tcg-1 was excised by cleavage with endonuclease EcoRI, re-cloned into the sequencing vector M13mp9 and sequenced by the Sanger dideoxy chain-termination method⁹. The DNA fragment encoding the surface antigen was 500 bp long, and contained a 27-bp repeat unit which occurred five times in tandem within the sequence (Fig. 4b). Degenerate repeats of 33 bp and 21 bp preceded and followed the five tandem repeats, respectively. Within the repeat unit, a single base change of $A \rightarrow G$ occurred once (nucleotide 223) and a $T \rightarrow C$ transition twice (nucleotides 189 and 215).

Since no protein sequence data are available for T. cruzi surface proteins, the amino-acid sequence encoded in the T. cruzi DNA fragment in Tcg-1 was deduced from the DNA sequence. The coding strand was determined by hybridization of poly(A)+ trypomastigote RNA to M13mp9 recombinants containing the two complementary DNA strands. A single open reading frame encoding 139 amino acids in frame with β galactosidase was observed. The predicted reading frame terminated with a TGA stop codon immediately followed by a second TGA codon 3 bp downstream. In this reading frame the $A \rightarrow G$ transition occurred in the second base of the code, resulting in a Glu → Gly amino-acid change. The T → C transition resulted in a third position change in Asp, but the amino acids remained unchanged. With regard to the two degenerate repeat units, the 33-bp unit was generated by the insertion of an additional Lys-Gly between amino acids 4 and 5 while the 21 bp partial repeat terminated prematurely at amino acid 7.

In summary, clone Tcg-1 encodes antigenic determinants present in the trypomastigote 85K surface antigen as well as a 76K protein. The relationship between the 85K and 76K proteins is unclear, but it is possible that the 76K protein represents either a precursor or breakdown product of the 85K surface protein. The observation that a 76K protein is not present in the IBSP preparation used in these studies and that the Tcg-1 DNA insert hybridizes to a single- M_r RNA argues in favour of one rather than two polypeptides being represented by the $T.\ cruzi$ DNA insert present in Tcg-1.

Fig. 4 a, Northern blot of poly(A)⁺ RNA from trypomastigotes (lane 1) and epimastigotes (lane 2), and total RNA from trypomastigotes (lane 3), epimastigotes (lane 4) and amastigotes (lane 5) hybridized to the 500-bp Tcg-1 insert DNA nick-translated with $[\alpha^{-32}P]$ dCTP to a specific activity of 2×10^8 c.p.m. per µg. Processing of the blot was as described previously¹⁷. b, Nucleotide sequence of the genomic DNA insert in Tcg-1. The sequence was determined by use of the dideoxy chain-termination method9 after subcloning the EcoRI fragment of Tcg-1 into M13mp9 in both directions 18. The reading frame is shown in phase with β -galactosidase and the TGA termination codons are

denoted by an asterisk (*). The repeat unit is indicated by the boxed regions and the partial repeat units are included in broken boxes. Códing strand preference was determined by hybridization of recombinant M13mp9 DNA with poly(A)⁺ trypomastigote RNA (data not shown).

One of the most interesting features of the Tcg-1 antigen is the presence of the tandem repeating regions; these are strikingly similar in architecture to tandem repeating regions in both the S-antigen and the circumsporozoite surface (CS) protein of Plasmodium¹⁰⁻¹⁴. As in the malarial proteins, the repeat unit is well conserved, with some base changes occurring in the third base of the codon, and thus no concomitant change occurring in the amino acid. Also, the repeat unit is rather small, with the more homogeneous core repeats being flanked by degenerate repeats. In addition, the repeat units are found in surface or secreted proteins whose synthesis is stage specific.

It would be of particular interest to determine the degree to which the repeat unit is conserved among different T. cruzi strains. It is known that the repeat units present in the CS protein of two strains of Plasmodium knowlesi12 and the repeat units present in the S-antigen of two strains of Plasmodium falciparum14 are totally divergent and share essentially no sequence homology. If this should be the case for the repeat unit in the 85K trypomastigote surface protein, the repeat unit might serve as a convenient means of identification of specific strains of the parasite by direct immunodiagnostic techniques.

We do not know what role the repeat unit may have in the biological function of the 85K surface protein, nor the function of the 85K protein in the life-cycle of the parasite. However, a more thorough knowledge of the conservation of the repeat among different T. cruzi isolates and the immunological properties of the repeat should elucidate its usefulness to the survival of the parasite in the host as well as its potential as a diagnostic antigen and/or a vaccine.

We thank J. Massey and B. Granger for technical assistance. This investigation was supported by NIH grant AII8873 and the UNDP/World Bank/WHO programme in tropical diseases.

Apparent eukaryotic origin of glutamine synthetase II from the bacterium Bradyrhizobium japonicum

Todd A. Carlson*† & Barry K. Chelm*‡

* Department of Energy Plant Research Laboratory, Departments of † Biochemistry and ‡ Microbiology and Public Health Michigan State University, East Lansing, Michigan 48824, USA

The Rhizobiaceae family of bacteria is characterized by the ability to form cortical hypertrophies on plants, and the ability to reisolate the bacteria from these galls or nodules1. This family includes the genera Rhizobium, Bradyrhizobium, Agrobacterium and Phyllobacterium. Another unique feature of these bacteria is that they contain two forms of the enzyme glutamine synthetase, termed GSI and GSII^{2,3}. GSI is typical of prokaryotic glutamine synthetases with respect to enzyme structure, the modulation of activity by post-translational modification, immunological crossreactivity, and amino-acid sequence^{2,4,5}. By contrast, GSII is distinct from all other known prokaryotic glutamine synthetases in structure and immunological reactivity, and is not known to be post-translationally modified. In these respects GSII is similar to eukaryotic glutamine synthetases. We have isolated and characterized the gene encoding GSII, which we term glnII, from Bradyrhizobium japonicum, the soybean symbiont. We show here that the amino-acid sequence of GSII, as inferred from the gene sequence, is highly homologous to plant glutamine synthetases, suggesting that this bacterial gene is of eukaryotic origin.

The GSII enzyme was purified as described in the Table 1 legend. This preparation was >95% pure as indicated by SDSpolyacrylamide gel electrophoresis. The amino-acid sequence of the amino terminus of GSII was determined by sequential Edman degradation and was used to design a mixed oligonucleotide probe with homology to the DNA which encodes the first six amino acids of GSII (Fig. 1a). An ambiguity at position 16 of the oligonucleotide was not included because two of the leucine codons, UUA and UUG, are infrequently utilized in B. japonicum. Two cosmids, pRjcos7-20 and pRJcos13-79, were isolated from a *B. japonicum* library constructed in the cloning vector pLAFRI^{7,8} by hybridization with radiolabelled oligonucleotide9,10. The region of hybridization in pRjcos7-20 was

Table 1 Purification of GSII					
Fraction	GSII activity (units)	Total protein (mg)	Specific activity (units mg ⁻¹)	Purification factor	Yield (%)
Extract Affi-Gel Blue DEAE HPLC fraction 17	149 39.1 9.92	48 0.89 0.12	3.10 43.9 82.7	(1) 14 27	(100) 26 6.7

Bradyrhizobium japonicum USDA 110 was grown to mid-log phase in 2 litre of MBX medium⁵ with 10 mM glutamate. Cell extracts were prepared by the method of Tronick et al.4 using GS buffer (GSB is 10 mM imidazole-HCl pH 7.15 and 1.0 mM MnCl₂). GS activity is expressed in units of μ mol of γ -glutamylhydroxamate per min. as measured by the reverse transferase assay²³. Heat inactivation of GSII was carried out on undiluted extracts by incubation at 58 °C for 30 min. In the extract used for purification, GSII accounted for 88% of the total GS activity. All purification steps were done at 4 °C. The extract was diluted with GSB to a protein concentration of 1 mg ml⁻¹ and loaded on a 10 ml Affi-Gel Blue (Bio-Rad) column at a flow rate of 0.5 ml min⁻¹. The column was washed with 50 ml of GSB and eluted with a 50-ml linear gradient of 0-5 mM ATP in GSB. A broad peak of GS activity, including both GSI and GSII, eluted immediately upon the initiation of the ATP gradient. The fractions with the highest specific GS activity were combined and loaded onto a Bio-Rad Bio-Gel TSK DEAE-5-PW ion-exchange HPLC column (75×7.5 mm) equilibrated with GSB, at a flow rate of 1 ml min⁻¹. The column was eluted with a 40-ml linear gradient of 0-500 mM KCl in GSB. The first and second peaks of GS activity corresponded to GSII and GSI respectively. Fractions (1 ml) for sequence determination were desalted on a 10 ml Bio-Rad P-6 column and lyophylized.

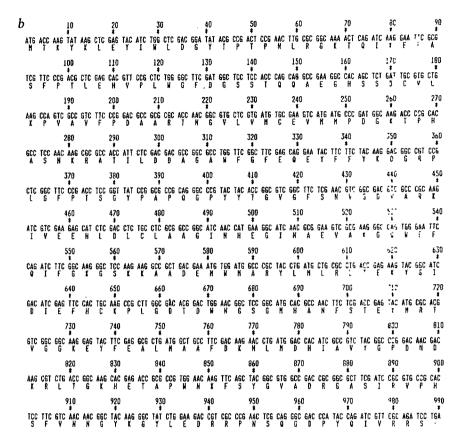

localized to 5.0 kilobase-pair (kbp) EcoRI, 1.0 kbp BglII and 2.1 kbp SalI fragments. These fragment sizes agree with those detected by hybridization to Southern transfers¹¹ of total genomic DNA restriction digests.

The 2.1-kbp SalI fragment with homology to the oligonucleotide probe was subcloned in both orientations in pBR322¹². The resulting plasmids, pBJ196A and pBJ196B, were tested for their ability to complement glutamine auxotrophy in Escherichia coli ET8051 [Δ (rha-glnA) hut C_K rbs nal^r]¹³. ET8051/pBJ196A grew well on defined medium plates with ammonia as the sole nitrogen source and yielded extracts with 0.82 units of GS activity per mg of protein. This GS activity was completely heat labile, a property specific to GSII, and co-sedimented with the GSII activity of B. japonicum in sucrose density gradient centrifugation. These data indicate that the entire glnII gene is located 2.1-kbp SalI fragment insert of pBJ196A. ET8051/pBJ196B, ET8051/pRjcos7-20 and the control strain ET8051/pBR322 gave no detectable growth on defined-medium

Fig. 1 a, The sequence of the amino terminus of GSII and the sequence of the mixed oligonucleotide hybridization probe used for gene identification. b, The complete DNA sequence of the coding region of glnII and the predicted amino-acid sequence of GSII.

Methods. Protein sequencing was performed on an Applied Biosystems Model 470A gas phase sequencer at the University of Michigan protein sequencing facility. Oligonucleotide probes were synthesized by the phosphoramidite method on an Applied Biosystems Model 380A synthesizer. Oligonucleotides were purified by denaturing 12% polyacrylamide gel electrophoresis²⁴. DNA was sequenced by the dideoxy-nucleotide chain termination method²⁵. Random fragments were generated by sonication²⁶ and subcloned into the SmaI site of M13-mp19²⁷. All regions were sequenced either on both strands or from three different fragments of the same strand. Plasmids were tested for their ability to complement glutamine auxotrophy in E. coli ET8051 on M9 defined-medium agar plates²⁸ with 0.2% glucose and 1 mM thiamine. GSI and GSII were separated by sucrose density gradient centrifugation as described previously⁵ except that the centrifugation was carried out at 50,000 r.p.m. for 3 h at 4°C.

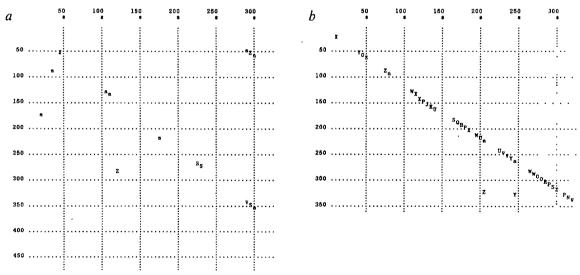

Fig. 2 Amino-acid homology matrices comparing B. japonicum GSII (x axis) to Anabaena 7120 (y axis, panel a) and Phaseolus vulgaris root GS (y axis, panel b). Homology matrices were plotted with the Pustel and Kafatos sequence analysis program¹⁷ using the following parameters: range = 11, scale factor = 0.75, minimum value = 47, compression = 5. Each letter represents a 2% extent of homology in that region of the matrix (A = 100-99%, B = 98-97% ... Z = 50-49%; a = 48-47%).

plates and produced no detectable glutamine synthetase activity. This indicates that the complementation observed with ET8051/pBJ196A was due to glnII expression from the tet promoter of the vector, in agreement with the gene orientation as indicated by sequence determination (see below).

In order to determine the precise location of the glnII gene, we sequenced the 2.1-kbp SalI fragment carried in pBJ196A.

The DNA sequence contains a single long open reading frame which encodes GSII (Fig. 1b). The relative molecular mass of the subunit of GSII, predicted by the complete amino-acid sequence, is 36,904, in good agreement with 36,000 as determined by SDS-polyacrylamide gel electrophoresis¹⁴. The amino terminus of GSII matches the protein sequencing data in 28 of 31 positions. The discrepancies at positions 24, 29 and 31 are

Table 2 Statistical significance of amino-acid sequence homologies between B. japonicum GSII and other glutamine synthetases

Glutamine synthetase source	% Identity to GSII	Similarity score	z yalue
Bradyrhizobium japonicum GSII	100	1719	208.4
Phaseolus vulgaris 16	43.8	663	77.3
Pisum sativum*	46.6	642	73.9
Medicago sativa ²¹	43.8	674	78.9
Nicotiana plumbaginifolia*	42.6	667	74.0
Anabaena 712013	24.4	114	8.83

All scores are from optimized alignments calculated with ktup = 1 and 1,000 randomized sequences using the RDF program of Lipman and Pearson¹⁸. The z value equals the similarity score minus the mean of the similarity scores with randomized sequences divided by the standard deviation of the randomized comparisons. A similarity score is considered significant if its z value is greater than 10 while z values less than 3 are not significant.

* G. Coruzzi, S. Tingey and B. Walker, personal communication.

presumably due to inaccuracies in the final cycles of the protein sequencing.

The comparisons of the B. japonicum GSII amino-acid sequence with the Anabaena 7120 GS15 and the Phaseolus vulgaris root GS16 sequences are shown as homology matrixes in Fig. 3. These matrixes were generated using the analysis program of Pustell and Kafatos¹⁷ with parameters set so that each letter within the matrix represents a match of 47%, or greater, over a span of 23 amino acids. It can be seen that GSII has only limited homology to the bacterial GS (Fig. 3a) but extensive homology to the plant GS (Fig. 3b).

GSII was compared with a variety of glutamine synthetases using the method of Lipman and Pearson 18 which optimizes the alignment between amino-acid sequences and quantitates the significance of the similarity (Table 2). Despite extensive homology among most prokaryotic glutamine synthetases, the homology between GSII and the typical bacterial glutamine synthetase of Anabaena 7120 is only marginally significant. In contrast, GSII has extensive homology with all eukaryotic glutamine synthetases that we have examined. Because all suggested cases of convergent evolution result in similarities of enzyme function without extensive sequence homology¹⁹, and because GSII is found only in the Rhizobiaceae³, we conclude that the B. japonicum glnII gene is the result of a eukaryote to prokaryote gene transfer event. We suggest that a plant served as the source of the progenitor glnII gene because of the plant pathogenic nature of the Rhizobiaceae.

The presence of the glnII gene in the Rhizobiaceae is the first evidence of gene transfer to symbiotic bacteria from the eukaryotic host. Another suggested example of eukaryote to prokaryote gene transfer, involving bacteriocuprein of Photobacterium leiognathi19, has recently come under dispute20

Although sequence homology suggests the origin of the glnII gene, questions pertaining to the mechanism, frequency or function of gene transfer between symbionts or pathogens cannot be directly addressed. Since plant GS genes are known to contain introns²¹, B. japonicum glnII had to evolve further by the loss of the introns, or the gene transfer must have occurred prior to the acquisition of introns in the plant genes. In addition, there is no obvious reason why the aquisition of a eukaryotic gene would confer a selective advantage on a plant symbiotic bacterium. GSII is not known to serve an essential function, acting only to provide extra ammonia assimilatory capacity during growth under nitrogen limited conditions²². Nevertheless, it appears that the ability to aquire genetic information from eukaryotes can be a source of genetic diversity in the evolution of bacteria.

We thank Tony Bleeker and Hans Kende for assistance in the HPLC analysis, Mike Shimei and Jan Watson for assistance in the oligonucleotide synthesis, Ron Davis for assistance in sequencing methods and analysis, and Benjamin Mifflin, Howard Goodman and Gloria Coruzzi for providing eukaryotic glutamine synthetase sequences before publication. Carotenoids serve as light-harvesting pigments and as photoprotective agents in photosynthetic organisms 1-9. Their role as antenna pigments involves absorption of photons in the blue-green spectral region followed by highly efficient singlet-singlet energy transfer to a neighbouring chlorophyll. The dependence of both the rate and mechanism of energy transfer on carotenoid-chlorophyll distance and orientation is unknown. Here, we have directly measured both the rate and efficiency of singlet energy transfer from a carotenoid covalently linked to pyropheophorbide a (PPheo a) in two model compounds, using picosecond transient absorption spectroscopy. In one model the π systems of the carotenoid and PPheo a possess a maximum edge-to-edge distance of 5 Å, while in the other model this distance is only 2 A. Energy transfer occurs from the carotenoid to PPheo a at the 2-A distance with a rate constant of $7\pm2\times10^{10}\,\text{s}^{-1}$ and $53\pm5\%\,$ efficiency, while energy transfer at the 5-Å distance occurs at a rate constant of $<3 \times 10^9 \, \text{s}^{-1}$ and with <5% efficiency. These results provide evidence that short distances and strong electronic interactions between carotenoids and chlorophylls are necessary to achieve the high energy transfer efficiencies observed in vivo.

The lifetimes of the lowest excited singlet state, S_1 of several carotenoids including β -carotene have been measured recently by transient absorption spectroscopy after direct excitation of the carotenoids with 4-ps pulses of 510-nm light¹⁰. That study showed that a combination of an unusually small radiative rate with an extremely fast rate of internal conversion results in carotenoid lifetimes that are of the order of 10 ps (for example, 8.4 ps for β -carotene). The short lifetimes of these states suggest that the rate of energy transfer from carotenoids to chlorophylls required to achieve very efficient energy transfer must be $>10^{11} \, \mathrm{s}^{-1}$. This requirement further implies that the electronic interaction between the carotenoid donor and the chlorophyll acceptor must be very strong¹¹⁻¹⁴.

The two model compounds that we studied (see below) differ in that the carotenoid moiety of compound (1) is linked to the

$$0 = C$$

$$0 = C$$

$$R' = -CH = CH_2, R' = -N$$

$$R' = -CCH_3$$

$$R' = -CCH_3$$

7-propionic acid side chain of the PPheo a via an amide bond, whereas in compound (2) the 2-vinyl group of methyl pyropheophorbide a has been replaced by a carboxylic acid which in turn has been linked to the same 4-aminophenyl carotenoid via an amide linkage. High-resolution ¹H-NMR spectroscopy of compounds (1) and (2) establishes that the time-averaged orientation of the carotenoid relative to the PPheo a in both (1) and (2) is such that the carotenoid is extended away from the macrocycle, rather than tightly folded back across the PPheo a. Thus, the maximum edge-to-edge distance between the carotenoid and PPheo a π system in (1) is \sim 5 Å, while that in (2) is \sim 2 Å. Moreover, in compound (2) the amide bond possesses a resonance structure which allows a degree of direct conjugation between the carotenoid and PPheo a π systems.

The rate and efficiency of energy transfer from the carotenoid to PPheo a in compounds (1) and (2) were determined directly by picosecond transient absorption spectroscopy. For this, solutions of compounds (1), (2) and carotenoid acetamide (3) (see below) were prepared in deoxygenated, spectral-grade toluene

and placed in cells with a 2-mm pathlength (A = 0.8). The optical absorption spectra of compounds (1) and (2) can be closely approximated as a simple superposition of the spectrum of compound (3) with that of the respective PPheo a derivative.

Figure 1 shows the transient absorption spectra of compounds (1)–(3) obtained at 0 ps relative to a 4-ps, 515-nm laser flash. In each case the carotenoid band is strongly bleached with a positive absorbance appearing near 560 nm. Similar spectral features have been observed previously for β -carotene and related carotenoids and are characteristic of carotenoid S_1 formation¹⁰.

Figure 2 shows the behaviour with time of the carotenoid

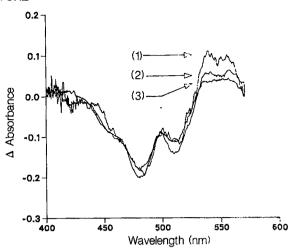

Fig. 1 Transient absorption spectra of the indicated compounds at 0 ps relative to a 4-ps, 25-µJ, 515-nm laser flash.

Methods. The 610-nm, 0.4-ps, 0.5-nJ output of a mode-locked Ar+-synchronously pumped R6G/DQOCI dye laser was amplified to 1.5 mJ using a four-stage R640 dye amplifier pumped by a frequency-doubled Nd-YAG laser operating at 10 Hz. The amplified laser pulse was split with a dichroic beam splitter. A 610-nm, 0.5-ps, 0.8-mJ pulse was focused into ethanol to generate a 5-µJ anti-Stokes Raman-shifted pulse at 515 nm. This pulse was amplified to 150 µJ using a two-stage coumarin-500 dye amplifier pumped by a frequency-tripled Nd-YAG laser. During amplification the 515-nm pulse broadened to 4 ps. The remaining 610-nm, 0.5-ps, 0.7-mJ pulse was used to generate a 0.5-ps whitelight continuum probe pulse. A 25-µJ, 515-nm pulse was used to excite a spot of 1 mm diameter on the sample cuvette. Absorbance measurements were made in a double-beam configuration which used optical multichannel detection. Delays between pump and probe pulses were achieved using an optical delay line. The absorbance of the carotenoid at 515 nm is ~7 times that of PPheo a in (1) and (2), and the carotenoid is therefore preferentially excited.

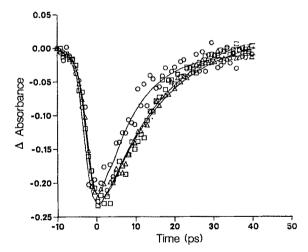

Fig. 2 Decay of the transient absorption at 480 nm of compounds (1) (\square), (2) (\bigcirc) and (3) (\triangle) following a 4-ps, 25- μ J, 515-nm laser flash. The solid curves are the best single exponential fits to the data.

absorbance changes at 480 nm. Each absorbance decays to zero with single exponential kinetics¹⁵, with $\tau = 15.9 \pm 0.8$, 7.6 ± 0.8 and 16.2 ± 0.8 -ps for compounds (1)-(3), respectively. Note that the time constant for recovery of the 480-nm bleach of the carotenoid in (1) is very similar to that of the carotenoid (3) alone, whereas the corresponding time constant for (2) is smaller than that of (3) by more than a factor of 2. From these results it is clear that the carotenoid S_1 population of (2) is depleted by an additional decay pathway that competes effectively with the intrinsic decay of the carotenoid S_1 state, whereas a similar competitive pathway in (1) is much less efficient.

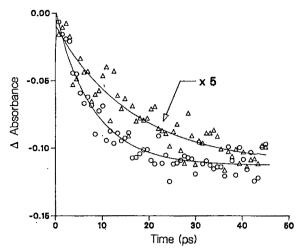

Fig. 3 Appearance of the transient bleach of compound (1) at 670 nm (\triangle) and of compound (2) at 675 nm (\bigcirc) following a 4-ps, 25-µJ, 515-nm laser flash: The absorbance change data for compound (1) are multiplied by 5 for comparison with those of compound (2). The solid curves are the best single exponential fits to the data.

Because the carotenoid does not absorb light at wavelengths >600 nm, this new decay pathway can be shown to be energy transfer to the attached PPheo a by examining the transient absorption changes of the PPheo a bands at 670 nm in (1) and at 675 nm in (2) after 515-nm excitation. Figure 3 shows the appearance kinetics of the bleach of these bands. The band at 675 nm in (2) bleaches with a 7.8 ± 0.8 -ps time constant whereas that of (1) bleaches with a 17.2 ± 0.8 -ps time constant. Also, the yield of S_1 of the PPheo a in (1) is much smaller than that of (2). The inverse of the time constant for the appearance of the PPheo a band bleach, which is the same as that for the recovery of the respective carotenoid bleach, is $k_{et} + k_{d}$, where k_{et} is the singlet-singlet energy transfer rate constant and k_d is the intrinsic carotenoid S_1 decay rate constant. Rate constant k_d is obtained from the S_1 decay of carotenoid (3). Thus, the rate of energy transfer for (2) is $7 \pm 2 \times 10^{10}$ s⁻¹, while that for (1) is $< 3 \times 10^9$ s⁻¹ based on the error limits of the measurements.

These results show that the carotenoid in compound (1) does not transfer energy efficiently to the PPheo a bonded to it. Better than 95% of the excited carotenoid molecules decay directly to ground state through their dominant radiationless pathways. On the other hand, the carotenoid in compound (2) transfers energy efficiently to the PPheo a. As no other decay mechanisms for S_1 are observed, the energy transfer efficiency is $k_{\rm et}/(k_{\rm et}+k_{\rm d})=$ $53 \pm 5\%$ for compound (2).

In conclusion, our results suggest that very strong electronic coupling between the π systems of a carotenoid donor and a chlorophyll derivative acceptor is necessary to achieve efficient singlet energy transfer rates. Strong electronic coupling between an energy donor and acceptor implies that terms involving orbital overlap must be included in the quantum mechanical description of the energy transfer mechanism¹¹⁻¹⁴. This in turn implies that in natural photosynthetic membranes where the coupling interaction is governed by the three-dimensional structure of the pigment-bearing proteins, the distances between donor and acceptor must approach van der Waals' contact. The successful characterization of singlet energy transfer in a welldefined model system augurs well for future direct measurement of energy transfer kinetics in natural photosynthetic antenna preparations.

Chloroplast gene organization deduced from complete sequence of liverwort Marchantia polymorpha chloroplast DNA

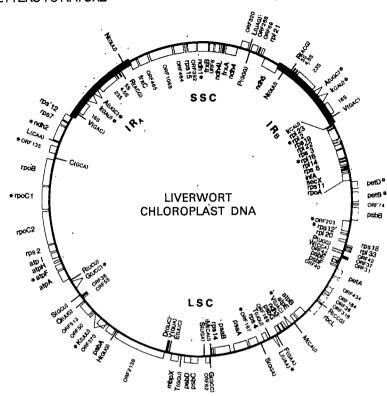

Kanji Ohyama*, Hideya Fukuzawa*, Takayuki Kohchi*, Hiromasa Shirai*‡, Tohru Sano*, Satoshi Sano*, Kazuhiko Umesono†, Yasuhiko Shiki†, Masayuki Takeuchi†, Zhen Chang†, Shin-ichi Aota†, Hachiro Inokuchi† & Haruo Ozeki†

* Research Center for Cell and Tissue Culture, Faculty of Agriculture, and † Department of Biophysics, Faculty of Science, Kyoto University, Kyoto 606, Japan

Chloroplasts contain their own autonomously replicating DNA genome. The majority of proteins present in the chloroplasts are encoded by nuclear DNA, but the rest are encoded by chloroplast DNA and synthesized by the chloroplast transcription-translation machinery 1-4. Although the nucleotide sequences of many chloroplast genes from various plant species have been determined, the entire gene organization of the chloroplast genome has not yet been elucidated for any species of plants. To improve our understanding of the chloroplast gene system, we have determined the complete sequence of the chloroplast DNA from a liverwort, Marchantia polymorpha, and deduced the gene organization. As reported here the liverwort chloroplast DNA contains 121,024 base pairs (bp), consisting of a set of large inverted repeats (IRA and IR_B, each of 10,058 bp) separated by a small single-copy region (SSC, 19,813 bp) and a large single-copy region (LSC, 81,095 bp). We detected 128 possible genes throughout the liverwort chloroplast genome, including coding sequences for four kinds of ribosomal RNAs, 32 species of transfer RNAs and 55 identified open reading frames (ORFs) for proteins, which are separated by short A+T-rich spacers (Fig. 1). Twenty genes (8 encoding tRNAs, 12 encoding proteins) contain introns in their coding sequences. These introns can be classified as belonging to either group I or group II, as described for mitochondria⁵. Interestingly, seven of the identified. ORFs show high homology to unidentified reading frames (URFs) found in human mitochondria^{6,7}.

The genes encoding the chloroplast rRNAs (16S, 23S, 4.5S and 5S rRNAs) were localized by Southern hybridization with specific rRNA probes⁸⁻¹⁰. DNA sequences also confirmed the presence of the rRNA operons in both inverted repeat regions. Genes encoding tRNAs were localized using the T ψ loop sequence (GTTCRA) and identified by constructing the familiar

Fig. 1 Gene organization of the chloroplast genome from a liverwort, Marchantia polymorpha. Thick lines indicate the inverted repeats (IRA and IRB). SSC and LSC indicate the small single-copy region and large single-copy region, respectively. Genes shown outside the map are transcribed anticlockwise, and those inside are transcribed clockwise. The tRNA genes are identified by the one-letter aminoacid code with their anticodons given in parentheses. Asterisks indicate genes having introns in their sequences. The genes for the 50S and 30S ribosomal proteins are shown as rpl and rps, respectively. atp, psa, psb and pet represent the genes for subunits of H⁺-ATPase, proteins in photosystem I, photosystem II, and cytochrome b_6/f complex, respectively. We tentatively designated chloroplast ORFs which exhibited homology to those found in human mitochondria, as ndh, ORFs which showed homology to 4Fe-4S proteins as frx, and inner membrane permease protein found in E. coli as mbp. infA and secX represent genes for initiation factor 1 and functionally unidentified protein expressed in E. coli, respectively. rbcL, the gene for the large subunit of ribulose bisphosphate carboxylase. rpoA, rpoB, rpoC1 and rpoC2 are the genes for RNA polymerase subunits. Ribosomal RNA operons are located in both IR regions (16S, 23S, 4.5S and 5S). Methods. For DNA sequencing, we first construct gene libraries from BamHI-, BglII-, PstI-, XhoI-, HindIII-, EcoRI-, BelI-, ClaI- and AluI-generated chloroplast DNA fragments using the plasmids pBR322, pKC7, pUC13, pUC18 and pUC19. These clones were used for DNA sequencing by the method of Maxam and Gilbert30, and the dideoxy chain termination procedure³¹. About 95% of the sequence of each clone was obtained from both

strands by the shotgun procedure³² and progressive deletion method³³, then the single-stranded region or ambiguities were resolved by the more directed enzymatic digestion method. We have sequenced both IR regions and found them to be identical. The data were compiled in computers using the program DNASIS (Hitachi SK Ltd.).

clover-leaf structure, except for tRNA^{Pro}_{GG} in which the aminoacyl stem structure is incomplete. We identified 37 tRNA genes encoding 32 species, including 5 duplicated ones in the inverted repeat regions. The accepting amino acids were deduced from their unmodified anticodons according to the standard codon table¹¹. The tRNAs encoded by the chloroplast genome are sufficient to read all codons, taking into account wobbling and modification in the anticodons¹² and assuming that no tRNA is imported from the cytoplasm¹³. An analysis of codon usage in the ORFs reveals a preference for A or U in the third position of the codons.

Significant open reading frames were identified using the universal codon table (AUG as the initiation codon; UAA, UAG and UGA as termination codons). The introns in the ORFs were predicted from the presence of the 5' consensus sequence (GUGYG) and 3' consensus secondary structures characteristic of group II introns found in fungal mitochondrial genes⁵. These significant ORFs were identified by computer search¹⁴ using the protein sequence database NBRF PIR Release 6.0. The genes identified on the chloroplast genome are summarized in Table 1.

Chloroplasts contain their own ribosomes (70S) which are active in protein synthesis. About one-third of the ribosomal proteins are encoded by the chloroplast genome and the remainder by the nuclear genome¹⁵. We identified genes encoding ribosomal proteins by comparing amino-acid sequences with homologous genes in Escherichia coli. Moreover, there are clusterings of S12-S7 and L23-L2-S19-L22-S3-L16-L14-S8-infA-secX-S11-rpoA genes in a similar order to the clusters that have been reported in the E. coli ribosomal protein operons, that is, the str operon (S12-S7-fus-tufA) and a large cluster of ribosomal protein genes consisting of three operons, S10 (S10-L3-L4-L23-L2-S19-L22-S3-L16-L29-S17)¹⁶-spc (L14-L24-L5-S14-S8-L6-L18-S5-L30-secY-secX)¹⁷-α and (S13-S11-S4-rpoA-L17)¹⁸, respectively; the genes found in chloroplast clusters are italicized. In contrast, the chloroplast genes rps2, rps4, rps14, rps15, rps18, rpl20, rpl21 and rpl33 were scattered throughout the

chloroplast genome¹⁹. We have reported previously that the coding sequence for the ribosomal protein S12 (*rps12*) is interrupted and located far apart on different DNA strands, suggesting the possibility of *trans*-splicing²⁰.

We also identified the genes rpoA and rpoB, which respectively encode the α - and β -subunits of E coli RNA polymerase. The coding region for the β' -subunit consists of two separate ORFs (rpoC1 and rpoC2, which correspond to the N-terminal and C-terminal halves of the β' -subunit, respectively), but this does not exclude the possibility of an intron lying between them (see Fig. 1). So far no gene has been detected corresponding to an E coli type of σ factor²¹.

The most important feature of chloroplasts is their role in photosynthesis. Complete sequence analysis of the liverwort chloroplast DNA has revealed that there are nine genes (psaA, psaB, psbA, psbB, psbC, psbD, psbE, psbF and psbG) in photosystems I and II. We also identified the genes encoding six of the nine subunits of H+-ATPase (atpA, atpB, atpE, atpF, atpH and atoI). In addition, we have identified and mapped three genes (petA, petB and petD) encoding proteins involved in the photoelectron transport system. The gene for the large subunit of a ribulose bisphosphate carboxylase (rbcL) is encoded by the chloroplast genome as expected, the small subunit being encoded by the nuclear genome. Our results revealed that the liverwort chloroplast genome is comparatively small (121,024 bp), nevertheless it possesses all the photosynthetic genes and others which have been reported previously in various plant species²², except the genes tufA (ref. 23) and rps16 (ref. 24). These results imply that the chloroplast genomes in plants from liverwort to higher plants, have basically the same gene composition.

We have described a number of ORFs which have not been reported or identified previously. Our computer analysis revealed seven ORFs (ndh1, ndh2, ndh3, ndh4, ndh4L, ndh5 and URF6) whose aminoacid sequences show significant homology (11.3-31.3% over their entire length, but much higher in specific

regions) to those of human mitochondrial genes (URFs)6. Six of the ORFs (URFs 1-5 and 4L) were identified as genes for components of the NADH dehydrogenase in human mitochondria⁷. There has been no previous report of the presence of these genes in the chloroplast genome. However, an NADH-plastoquinone-(PQ) oxidoreductase activity has been detected in the chloroplasts of Chlamydomonas reinhardii25, thus it is possible that these ORFs encode subunits of the NADH-PQ oxidoreductase. There are two cysteine-rich ORFs (frxA and frxB) in which the periodic appearance of cysteines is typical of that in 4Fe-4S ferredoxin²⁶, and an ORF (frxC) whose amino-acid sequence is highly homologous (44.3%) to that of the ORF in the photosynthetic gene cluster of *Rhodopseudomonas capsulata*²⁷. These findings imply that basic genes which encode components of the large subunit of ribulose biphosphate carboxylase photosystem I, H⁺-ATPase, the cytochrome b_6/f complex, photosystem II and NADH-PQ oxidoreductase, all reside on the chloroplast genome. These functionally related gene groups are to some extent clustered in the chloroplast genome (see Fig. 1).

Thus, the liverwort chloroplast genome contains genes encoding the transcription-translation system as well as genes for protein complexes involved in chloroplast photosynthesis.

However, it seems that no functionally active complex is formed without nuclear-encoded protein subunits. Strikingly, chloroplasts and mitochondria have been found to have genes with a common function, in particular, the genes encoding H⁺-ATPase; NADH dehydrogenase and the cytochrome complex²⁸. These observations can be interpreted as suggesting that chloroplasts and mitochondria arose from a common ancestor. Further detailed information obtained from the complete sequencing of liverwort chloroplast DNA will be published elsewhere (but liverwort chloroplast DNA sequence data are available on request).

Unidentified genes More than 28 ORFs

We thank Dr C. J. Leaver for critical reading of the manuscript, and Drs T. Maruyama and T. Ikemura for computer analysis. We also thank Drs Y. Uchida and Y. Yamano for their preparations of chloroplast DNA clones, and Y. Yamashita, T. Tanaka, S. Asano and M. Toda for their assistance in DNA sequencing. We appreciate the continued support and encouragement of Dr Yasuyuki Yamada, Director of the Research Center for Cell and Tissue Culture. Faculty of Agriculture, Kyoto University. This research was supported in part by a Grant-in-Aid for Special Research Projects from the Ministry of Education, Science and Culture of Japan, and in part by the Yamada Science Foundation (H.O.).

Tradition takes an unexpected turn

New equipment and methodology keep breaking old moulds. This week an all-purpose robot rides on the ceiling, mussels make tissue culture a sticky situation and a fungus fights the planthopper that feeds it.

A microdialysis probe that acts as an "exogenous blood vessel" could help monitor the activities of neurotransmitters and the effects of neurotoxins (Reader Service No. 100). The probe represents the combined efforts of Carnegie Medicine in Sweden and a research team at the Karolinska Institute, who sought to find a technique that could dynamically follow chemical events in living tissue. Using two concentric steel cannulas tipped with a dialysing membrane, the collaborators found that substances diffuse across the membrane when a physiological fluid enters through the inner cannula, flushes the inside of the membrane and exits through the outer cannula. Hence Carnegie's probe can recover endogenous substances without removing fluid and introduce exogenous substances without injecting liquid. Although the concept originated with studies of the brain, the company now supplies probes for different purposes and locations within the body. An

Fisher keeps its robot in suspense, but the Maxx-5 can work on solid ground as well. The robot runs on an IBM PC that can manage both the robot and the data it collects.

A simple solution for complex studies.

assortment of membranes is also available with molecular weight cut-offs between 5,000 and 50,000. Complete instrumentation for microdialysis includes the probe, a pump and a liquid switch, but Carnegie also manufactures tools for subsequent fraction analysis by liquid chromatography.

Low overhead

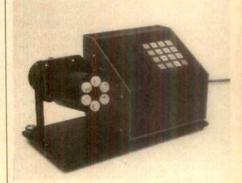

It weighs 30 lb. runs by computer and costs between \$30,000 and \$50,000 (US) and it won't get in the way (Reader Service No.101). Fisher's Maxx-5 robot can be mounted on laboratory ceilings or overhead frames using a motorized track that

can propel it along at a foot per second. The track, which also mounts on benchtops, adds a sixth dimension to Maxx-5's five-axis articulated arm. With adjustable grip strength, programmable arm speed and the aid of an IBM PC, the robot will dilute, mix, centrifuge, pipette, filter, concentrate and separate samples. Its fingers can hold beakers with up to 800 ml of solution. Maxx-5 also reads bar coding, so it can process samples according to individual labelling rather than by relying on station position. At this year's Pittsburgh Conference, the company said that Maxx-5 drew 570 inquiries. Fisher has a brochure entitled "Partners in Productivity" that describes the system in greater detail. The personal computer, software. linear track and numerous appliances are available as accessories.

Making the gradient

High reproducibility and convenience have rarely been the hallmarks of sucrose gradient generators. But a fresh approach from a professor at Canada's University of New Brunswick may turn gradient making around (Reader Service No. 102). According to inventor David Coombs. BioComp's model 105 will generate six identical sucrose gradients in 2.5 min without requiring any user supervision. Tubes that have been layered half and half with heavy and light sucrose are put in the instrument. It then tilts them to a predeter-

mined angle and rotates them for a pre-set time, at a pre-set speed. Different and pre-dictable gradient distributions result from different combinations of angle, time and speed. These parameters can be stored in the 105's non-volatile computer memory. Interchangeable holders will accommodate most tube sizes. At about \$1,900

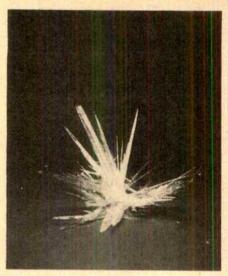

An innovation in reproducible gradients.

(US). Coombs says that the model is "more expensive, but less trouble" than traditional two-chamber devices.

Mussel power

The same adhesive that keeps the common blue mussel anchored to rocks and piers can now be used to attach cells and tissue to glass, plastic and even Teflon (Reader Service No. 103). Connecticut based BioPolymers Inc supplies the pro-

Skeletal imposters

THIS PRISTINE form belies its origin in oil and sediments far beneath the Earth's surface (Reader Service No. 104). The crystalline (18\(\beta\text{H}\))-olean-12-ene-3-one pictured is just one of the many substances that clutter petrochemical and geochemical analyses. In the search for oil in particular, reliable internal standards for analysis equipment are necessary to ensure the authentic identification of deposits. Recently, high purity "biomarkers" have emerged in the fossil fuel industry as dependable reference sources. These markers mimic the carbon skeletons of the organisms from which oil deposits are formed. By calibrating gas chromatography and mass spectrometry equipment with these synthetic markers, the distribution, history and progressive transformation into fossil fuel of the genuine organisms can be "unearthed".

tein, which it calls Cell-Tak, in 2 mg quantities of sterile aqueous solution for \$90 (US). The company claims Cell-Tak works rapidly with virtually any substrate: typically greater than 80 per cent of cells attach within 10 min of seeding, suggesting a diffusion-limited process. The adhesive does not alter cell morphology or doubling time and its effects appear to be independent of cell type. BioPolymers has already tested its product with anchorage-dependent cell lines such as vascular endothelium, as well as anchorageindependent lines such as U-937 human lymphoma. The company must shell, by hand, about 3 million mussels to extract 1 lb of Cell-Tak' adhesive. Thankfully, it takes only 50µl of Cell-Tak to coat a 35 ml Petri dish.

Instant access

The British Bureau of Hygiene and Tropical Diseases now provides several comprehensive current awareness services on AIDS and retroviruses (Reader Service No. 105). The bureau's update service publishes monthly an annotated bibliography of all the papers and articles on AIDS that the bureau has located, grouped by subject category. The update subscription rate is £80 (UK) or \$160 (US). Selected papers on AIDS and retroviruses also make it into one of the bureau's two abstract journals, and an AIDS newsletter has been established to cover the main AIDS news stories and commentaries on scientific developments. The BHTD recently made both the update and the abstract journals available for on-line searching through CAB International. These services are also on DataStar and BRS Information Technologies.

A free literature search from Radiometer Analytical can bring a wealth of experience as close as the telephone (Reader Service No. 106). Radiometer compiled selections from its applications library into a computer data base, organised by key words such as ion species or sample types. RADABASE now contains more than 1,500 references on Radiometer equipment use and misuse. The company supplies hard copies of the search for every request.

Small wonder

A cell disrupter for small samples uses minute glass beads and violent agitation to accomplish its ends (Reader Service No. 107). The Mini-BeadBeater, a recent release from Biospec Products in Oklahoma, uses a sealed polypropylene chamber within which 1 ml of beads will disrupt about 1 ml of sample in 1 to 3 min. Biospec

Small-scale destruction from Biospec

says that the collisions of the glass beads will crush even tough samples, like bone or microbial spores, without foaming or aerosol formation. The company thinks its system is safe for isolating enzymes and organelles or for extracting nucleic acids by phenol/chloroform procedures. In addition to applications with biological materials. Biospec recommends the Mini-BeadBeater for wet milling and emulsifying non-biologicals such as soil, paint pigments and pharmaceutical samples. With 15 disposable vials, two bead sizes optimized for eukaryotic or bacterial disruption and a 0.62 amp motor, the instrument sells for \$365 (US).

Beckman has tilted its latest spectrophotometry system towards the nucleic acid researcher, with a design that accommodates sample volumes of less than 50 µl (Reader Service No. 108). The company says its Micro-Leader package gives repeatable measurements and virtually full recovery that simplify purity analyses in DNA preparation. Beckman

Beckman's spectrophotometer is made for minute samples.

credits this performance to the microvolume cuvette and cell holder that it designed specifically for the Micro-Leader
system. With this cuvette samples are inserted and removed with a micropipette or
pasteur pipette. The full \$8,800 (US) system includes a DU-50 spectrophotometer
and a software applications module with
five procedures for purity assessment by
ratio methods. These programs, says
Beckman, reduce wavelength selection,
measurement and calculation to a few key
strokes.

Courses of action

Hands-on experience with sophisticated techniques can be a rarity for biology undergraduates, so a Purdue professor decided to pull together the materials and literature needed to teach them electrophoresis (Reader Service No. 109). Today the electrophoresis educational kits are marketed by Indiana-based Biostar Corp. Biostar adapted research procedures for use in student laboratories, and now even high schools are taking advantage of the opportunity — they comprise 25 per cent of sales. The kits are divided into three different levels of user experience and each provides the chemicals, equipment and manuals for about 16 students. Biostar considers its product a helpful boost into a biotechnology career.

Time for quick decisions: prices are about to go up on LC Resources' five-hour video primer for HPLC (Reader Service No. 110). The course, entitled "Getting Started in HPLC", covers the basic aspects of the chromatography method in five modules that can be purchased separately or as a \$1.795 (US) package. Pricing may limit the feasibility of the course to group training.

and LC Resources expects to raise its price to \$2,250 (US) in September. But the company guarantees the programme with complete "credit" (presumably not a refund) on returns within 30 days, and negotiates discounts for multiple orders. Video tapes come in 1/2-inch VHS and 3/4-inch U-Matic formats.

Savant's 10th anniversary catalogue gives a run-down of current training programmes in analytical, clinical and chemical instrumentation, along with three of the California company's latest additions (Reader Service No. 111). The new programmes include: training for inductively coupled plasma MS, enzyme immunoassays and gas chromatography analysis. The latter two programmes are authored by William Ulrich at Smith-Kline Beckman and Virginia Polytechnic's Harold McNair, respectively. Savant provides its training courses as slides or video tapes. The slide packages contain about 50 slides, a script and a cassette tape: the videos are available in VHS

Savant trains all types.

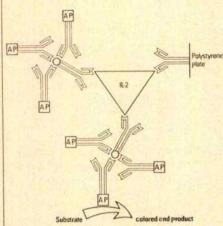

or Beta formats. Savant says the courses last about 45 minutes, and prices are listed in the catalogue.

The AIDS brigade

Earlier this summer. Du Pont announced the arrival of a radioimmunoassay that directly detects a structural core protein of the AIDS virus, HTLV-III (Reader Service No. 112). Du Pont says that its method is 25 to 200 times more sensitive than reverse transcriptase assaving and cuts cell culturing time down to as few as 3 days. The kit, which is at present available for research purposes only, measures viral activity as represented by the amount of p24, a core protein. According to the company it "virtually eliminates cross reactivity with other human cellular and viral proteins, and has been able to detect all human AIDS-associated retroviruses tested to date". Du Pont includes

recombinant human interleukin-2 in the kit to amplify cell growth in culture. Assays can be performed in less than a day. Du Pont charges S650 (US) for the kit, which contains enough material for 125 assays.

A scheme for detecting human interleukin-2 using monoclonal antibodies hit the market recently when Genzyme Corp in

The final step in Genzyme's analysis

Boston introduced its InterTest-2 kit (Reader Service No. 113). Taking less than 8 hours to complete, the ELISA-based technique is distributed for research use only and can detect IL-2 in serum, blood and other biolo-

gical fluids, says Genzyme. The company collaborated with a Boston group called Endogen to produce the kit, and expects the assay to speed IL-2 research into cancer and AIDS treatment. Genzyme sells InterTest-2 kits for \$395 (US) each, and each kit can perform up to 84 tests.

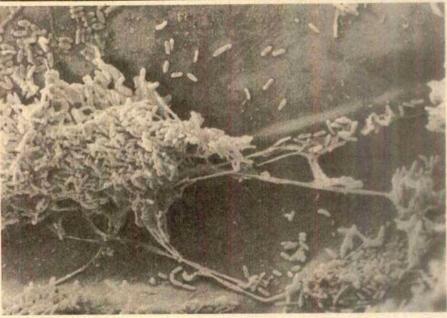

Dealing with DNA

Applied Biosystems keep experimenting with the chemistry for their DNA synthesizers, and they are now producing strands up to 175 bases long (Reader Service No. 114). AB's model 380B synthesizer is one of a family of machines capable of this sort of

New chemistry boosts Applied Biosystems synthesizer.

production. Using β-cyanoethyl phosphoramidite methods, the 380B routinely gener-

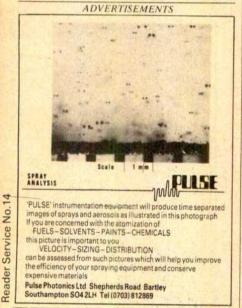

Spore wars

This seemingly sedate micrograph actually depicts a vicious attack by the green fungus Metarhizium anisopliae upon the brown planthopper Nilaparvata lugens (Reader Service No. 115). Three researchers at King's College, London and the Berkshire company Microbial Resources plan to make M. anisopliae even more adept at victimizing the planthopper, which causes serious losses to rice crops in China, Japan, Korea and India. The investigators want to exploit the

microbe's role as a natural pesticide. Using techniques for genetic recombination, such as somatic hybridization and traditional heterokaryon fusion, they hope to increase the fungus's effectiveness in the field. Already the team has isolated one recombinant that gives nearly twice the total spore production and over 1,000 times the ease of spore release of either parent. These improvements have so far been achieved without any adverse effects on M. anisopliae's growth rate.

ates 50- to 100-mers and quantities that range from primers and probes up to 10 mg for physical studies. Coupling yields vary between 98 and 100 per cent. according to AB. A single-column instrument costs \$45,000 (US) and a 5-column, \$49,500 (US). A menu-driven touchscreen control allows the user to operate standard synthesis cycles including automatic deprotection and cleavage), or develop new procedures.

Two new synthesizers from Biosearch in California have also been making their mark (Reader Service No. 116). The models 8650 and 8750 have one and four columns, respectively, and according to Biosearch have been producing DNA fragments up to 180 bases in length. An IBM PC/AT computer workstation manages the unit, stores sequence and protocol data and simplifies sequence entry and editing. Biosearch mentions that the computer can also be connected via a modem to libraries of DNA

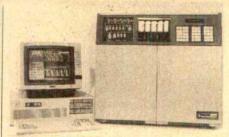

Eliminates evaporation loss and contamination. Easy to use — flush with gas mixture, seal, place at appropriate temperature. Stackable, see-through. Quantity discounts. billups-rothenberg, inc., pob 977, Del Mar, CA USA 92014. Call 619-755-3309 or contact your Flow Laboratories representative.

Biosearch is joining the synthesizer league.

sequences and to software that could translate sequences into protein equivalents. The IBM will control up to eight of Biosearch's instruments, which cost \$42.900 and \$53.900 (US), depending on the number of columns, and use \$\beta\$-cyanoethyl phosphoramidite chemistry.

Proteins A and G

An alternative to protein A as an immunological reagent has come from Amersham in the form of protein G, a bacterial cell wall protein with a high affinity for the Fc region of a range of immunoglobulins (Reader Service No. 117). Amersham lists among protein G's advantages high affinity binding to IgGs from rat, goat and sheep and binding almost exclusive to IgG without crossreactions with other classes. The reagent, according to Amersham, also binds to a wider range of species IgG and subclasses than protein A. But the company suggests

that ultimately its E-labelled protein G would best be viewed as a complement to protein A. As such, it could be particularly useful in blotting procedures to detect specific IgGs, in the study of antigenantibody interactions and for antibody screening where protein A fails to bind.

Two fusion vectors and a revised Sepharose gel put the punch into Pharmacia's system for the production, purification and characterization of protein A fusion protein conjugates (Reader Service No. 118). The company's fusion system uses the two vectors to induce high levels of expression of intracellular proteins (vector pRIT2T) and of proteins transported to the periplasmic space or secreted (pRIT5). According to Pharmacia, conjugates thus produced in prokaryotic expression systems can be purified in a single step owing to improved mechanical characteristics of IgG Sepharose 6 gel. The company points out that the repetitive structure of the protein A moiety may enhance the immune response, making conjugates well-suited for direct immunization. Immunological assays will also provide rapid detection due to the protein A tail.

Good references

A simple test for pipetters can provide reassurance when the instruments are accurate and warning when they go on the blink (Reader Service No. 119). Bel-Art Products supplies an accuracy test kit that determines whether pipettes from Gilson, Eppendorf, Oxford, Finn and other manufacturers still conform to those brands' specifications for precision. An adaptor slips into the pipetter tip, then a capillary is inserted in the adaptor's distal end. Next the pipetter plunger is depressed, the capillary immersed in water and the plunger slowly released. The liquid level in the capillary should be within 1.5 mm of Bel-Art's mark on the glass; otherwise, the pipetter is not performing within manufacturer's specifications. The \$87 (US) kit has two soft adaptors and six different sizes of glass inserts to adjust for volumes between I and 1,000 ul.

A set of nine mercury-filled thermometers may look ordinary but carry a hidden value: Brooklyn Thermometer Co's reference set has NBS traceable certification (Reader Service No. 120). The yellowback glass thermometers cover the temperature range between -36° and 761° F. Brooklyn guarantees fractional degree accuracy for one year and charges \$1,124 (US). The set comes with factory certificates and corrections for the five text points on each thermometer, as required by the American Society for Testing and Materials.

These notes are compiled by Karen Wright from information provided by the manufacturers. To obtain further details about these products, use the reader service card bound inside the journal. Prices quoted are sometimes nominal and apply only within the country indicated.

Differential Calculus. By A. AVEZ. Wiley:1986. Pp.179. Hbk ISBN 0-471-90873-8. Np.

I Want to be a Mathematician, an Automathography. By PAUL R. HALMOS. Springer-Verlag:1985. Pp.421. Hbk ISBN 0-387-96078-3/3-540-96078-3. \$41.50.

Introduction to Mathematical Control Theory, 2nd Edn. By S. BARNETT and R.G. CAMERON. Oxford University Press:1985. Pp. 404. Hbk ISBN 0-19-859640-5. £25.

Measures on Infinite Dimensional Spaces. Series in Pure Mathematics Vol.5. By Y. YAMASAKI. World Scientific Publishing: 1985. Pp. 256. Hbk ISBN 9971-978-52-0. £22.

Numerical Methods for CAD. Mathematics and CAD. Vol.1. By YVON GARDAN. Kogan Page, 1985. Pp. 165. Hbk ISBN 0-85038-817-1. £18.

Stochastic System Reliability Modeling. By SHUNJI OSAKI. World Scientific:1985. Pp.285. ISBN 9971-978-56-3. £23.90.

Turbulence and Diffusion in Stable Environments. The Institute of Mathematics and its Applications Conference Series, New Series No.4, J. C. R. HUNT (ed.), Clarendon Press: 1985. Pp.319. Hbk ISBN 0-19-853604-6. £32.

Physics

Acoustical Imaging, Vol.14. A.I. BERKHOUT, J. RIDDER, and I.F. VAN DER WAL (eds). Plenam: 1985, Pp.801, 11bk ISBN 0-806-42094-5, Np.

Advances in Atomic and Molecular Physics, Vol.21.
DAVID BATES and BENJAMIN BEDLERSON (eds). Academic:1985. Pp.382. 116k ISBN 0-12-003821-8, E85, 50, 899.

Advances in Nuclear Physics. Vol.16. J.W. NEGELL and ERICH VOGT (eds.). Plenum:1986. Pp.327. Hbk ISBN 0-306-41997-1, Np.

Antinucleon— and Nucleon-Nucleus Interactions. GEORGI: E. WALKER, CHARLES D. GOODS-MAN and CATHERINE OLMER (eds.). Plenum: 1985. Pp.504. Hbk ISBN 0-306-420888. Np.

Applied Superconductivity, Metallurgy and Physics of Titanium Alloys, Vol.1, Fundamentals, E.W. COLLINGS, Plenum: 1986, Pp.808, Ilbk ISBN 0-306-41690-5, Np.

The Concept of Physical Law. By NORMAN SWARTZ. Combridge University Press: 1985. Pp. 220. Hbk. ISBN 0-521-25838-3: £22.50, \$29.95.

A Course of Experiments with He-Ne Laser. By R. S. SIROHI. Wiley 1985. Pp. 108. Hbk. ISBN 0-470-20250-5-16.60.

Diffusion: Mass Transfer in Fluid Systems. By E.L. CUSSLER. Cambridge University Press: 1986. Pp. 525. Pbk ISBN 0-521-29846-6. £15. \$24.95.

Elements of Relativity Theory. By D.F. LAWDEN. Wiley: 1985. Pp. 108. Pbk ISBN 0-471-90852-5. Pbk

Equilibrium Capillary Surfaces. By ROBERT FINN. Springer-Verlag 1986. Pp.245. Hbk ISBN 3-540-96174-7. DM 158.

Finite Element Methods in Linear Ideal Magnetohydrodynamics. By RALF GRUBER and JACQUES RAPPAZ. Springer-Verlag:1985. Pp.180. ISBN 3-540-13398-4-0-387-13398-4. DM 110.

The Free-Lagrange Method. Lecture Notes in Physics, Vol.238. M.J. FRITTS, W.P. CROWLEY and H. TREASE (eds). Springer-Verlag:1985. Pp.313. Phk 18BN 3-540-15992-4. DM 45.

From SU(3) to Gravity. ERROL GOTSMAN and GERALD TAUBER (eds). Cambridge University Press:1986. Pp. 457. Hbk ISBN 0-521-30784-8. \$59.50.

Fundamentals of Hot Wire Anemometry. By CHARLES G. LOMAS. Cambridge University Press: 1986. Pp.211. ISBN 0-521-30340-0-135, \$52.50.

General System Theory. Cybernetics and Systems Series. By ANATOL RAPOPORT. Abacus Press: 1986. Pp.270. Hbk ISBN 0-85626-172-6. £24.50. \$34.50.

Geometric Aspects of the Einstein Equations and Integrable Systems. Lecture Notes in Physics, Vol.239. R. MARTINI (ed.). Springer-Verlag: 1985. Pp. 344. Pbk ISBN 3-540-16039-6. DM 45.

Infrared and Millimeter Waves, Vol.13, Millimeter Components and Techniques (Part IV), KENNETH J. BUTTON (cd.), Academic:1985, Pp.363, Hbk ISBN 0-12-147713-4, £75, \$85.

Infrared and Millimeter Waves. Vol.14, Millimeter Components and Techniques, Part V. KENNETH J. BUTTON. Academic:1985. Pp. 418. Hbk ISBN 0-12-147714-2. £87, \$99.

Magnetic Resonance Annual 1986. HERBERT Y. KRESSEL (cd.). Raven Press:1985. Pp.267. Hbk ISBN 0-88167-155-X. \$64.

Mossbauer Spectroscopy and its Applications. By T.E. CRANSHAW, B.W. DALE, G.O. LONG-WORTH and C.E. JOHNSON, Cambridge University Press; 1986. Pp. 119. Hbk ISBN 0-521-30482-2; pbk ISBN 0-521-31521-2. Hbk I20, \$29.95; pbk I7.95, \$12.95.

Multiple Photon Infrared Laser Photophysics and Photochemistry. By V.N. BAGRATASHVILI, V.S. LETOKHOV, A.A. MAKAROV and E.A. RYABOV. Harwood Academic Publishers:1985. Pp.512. Hbk ISBN 3-7186-0269-5, 865.

Nuclear Statistical Spectroscopy. By S.S.M. WONG. Oxford University Press: 1986. Pp. 241. ISBN 0-19-504004-X. £25.

On Growth and Form: Fractal and Non-Fractal Patterns in Physics. H. EUGENE STANLEY and NICOLE OSTROWKY (eds). Martinus Nijhoff: 1986. Pp.308. ISBN 90-247-3234-4. Np.

Optical Interferometry. By P. HARIHARAN. Academic:1986. Pp.303. Hbk. ISBN 0-12-325220-2. L49.50, \$58.

Permanent-Magnet and Brushless DC Motors. By T. KENJO and S. NAGAMORT. Oxford University Press:1986. Pp.194. ISBN 0-19-856217-9. Hbk £25: pbk £9.95.

Physics and Technology of Nuclear Materials. By IOAN URSU. Pergamon: 1985. Pp. 528. Hbk ISBN 0-08-032601-3, £45.50, \$59.50.

Principles and Methods of Nuclear Geophysics. By V.L.S. BHIMAŠANKARAM. N. VENKAT RAO. K. SRIRAMA MURTI and E.I. SAVENKO. Association of Exploration Geophysicists. Osmania University Campus, Hyderabad, 500 007. India:1985. Pp. 325. Hbk 850.

The Propagation of Radio Waves: The Theory of Radio Waves of Low Power in the Ionosphere and Magnetosphere. By K. G. BUDDEN. Cambridge University Press: 1985. Pp. 669. ISBN 0-521-25461-2. £60, \$89.50.

Quantum Electrodynamics of Strong Fields With an Introduction into Modern Relativistic Quantum Mechanics. By W. GREINER B. MÜLLER and J. RAFELSKI. Springer-Verlag: 1985. Pp. 594. Hbk. ISBN 3-540-13404-2. DM 140

Quantum Physics: Illusion or Reality? By ALISTAIR RAE. Cambridge University Press:1986. Pp.123. Hbk ISBN 0-521-26023-X, £17.50, \$29.95.

Quark Model and High Energy Collisions. By V.V. ANISOVICH. M.N. KOBRINSKY. J. NYIRI and YU M. SHABELSKI. World Scientific: 1985. Pp. 435. Hbk ISBN 9971-966-68-9. £29-80.

Radionuclide Imaging Techniques. By PETER F. SHARP. PHILIP P. DENDY and W. IAN KEYES. Academic:1985. Pp.271. Hbk ISBN 0-12-639020-7; pbk. ISBN 0-12-639021-5. Hbk £58, \$63.50; pbk £34.95, \$88.95.

Rate Equations in Semiconductor Electronics. By J.E. CARROLL. Cambridge University Press:1986. Pp. 177. Hbk ISBN 0-521-26533-9, 125, 339-50

Renormalization. By JOHN COLLINS. Cambridge University Press:1986. Pp.380. Pbk ISBN 0-521-31177-2, £13-95

Stability of Parallel Gas Flows. By B.K. SHIVA-MOGGI. Ellis Horwood/Wiley:1986. Pp.169. Hbk ISBN 0-7458-0001-7, £20.

Teaching Thermodynamics. JEFFREY D. LEWINS (ed.). Plenum:1985. Pp.517. Hbk ISBN 0-306-42207-7. Np.

Thin Films From Free Atoms and Particles. KENNETH J. KLABUNDE (ed.). Academic:1986. Pp.363. Hbk ISBN 0-12-410755-9. £51, 860.

VLSI Handbook, NORMAN G. EINSPRUCH (ed.) Academic:1985. Pp.902. ISBN 0-12-234100-7. \$125. £107.50.

Environmental Sciences

Atmospheric Chemistry and Physics of Air Pollution. By JOHN H. SEINFELD. Wiley 1986. Pp. 738. Hbk ISBN 0-471-82857-2. £61.35.

Epidemiology and Quantitation of Environmental Risk in Humans from Radiation and Other Agents. A. CASTELLANI (ed.). Nato ASI Series. Plenum: 1985. Pp. 584. iibk ISBN 0-306-42093-7. Np.

Industrial Hygiene Aspects of Plant Operations. Vol. 1, Process Flows. LESTER V. CRALLEY and LEWIS J. CRALLEY (eds). Collier Macmillan: 1985. Pp. 630. Hbk ISBN 0-02-949350-1. £70.

Industrial Hygiene Aspects of Plant Operations. Vol.3, Engineering Considerations in Equipment Selection, Layout and Building Design. LESTER V. CRALLEY, LEWIS J. CRALLEY and KNOWLTON J. CAPLAN (eds). Collier Macmillan: 1985. Pp. 785. Hbk ISBN 0-02-949370-6, £65.

Management of Toxic and Hazardous Wastes, H.G. BHATT, ROBERT M. SYKES and THOMAS L. SWEENEY (eds). Lewis Publishers, Michigan, US:1985. Pp.418. Hbk ISBN 0-87371-023-1_£43-95.

Marine Pollution. By R.B. CLARK. Oxford University Press:1986. Pp.215. Hbk 18BN 0-19-854183-X; pbk 1SBN 0-19-854182-1. Hbk £19.50; pbk £9.95.

Oil in the Sea: Inputs, Fates and Effects. OCF AN SCIENCES BOARD. National Academy of Sciences, Wiley:1985. Pp.601. ISBN 0-309-03479-3. £41.80.

Solid Waste Management: Selected Topics. MICHAEL J. SUESS (ed.). World Health Organization. Regional Office for Europe. Copenhagen: 1985. Pp. 210. Pbk 18BN 92-890-1023-1. SwFr. 15

Biological Sciences

*Atlas of Diseases of the Oral Mucosa. By J.J. PIND-BORG. Munksguard: 1985. Pp. 357. ISBN 87-16-09880-3. DKr. 500.

Butterfly and Caterpillar. By BARRIE WATTS. A&C Black: 1985. Pp. 25. ISBN 0-7136-2709-3, £3.95. Chirotteri Italiani. By DOMENICO SCARA-MELLA. Edagricole. Casella Postale 2202, 40139 Bologna, Italy: 1985. Pp. 124. Pbk ISBN 88-206-2517-2, Pbk L 12.

Chronological Phenomena in Plant Communities, R. NEUHÄUSL, H. DIERSCHKE and J.J. BARK-MAN (eds). Dr. W. Junk:1985. Pp. 270. ISBN 96-6193-515-6. Djl. 225. 875, £62.56.

A Colour Atlas of Virology. By JAN VERSTEEG. Wolfe Medical Publications, 3 Conway Street, London W1P 6HE, UK:1985, Pp.240, ISBN 0-7234-0808-4, £60.

Communication in the Chiroptera. By M. BROCK FENTON. Indiana University Press: 1985. Pp. 361-ISBN 0-253-31381-3. \$35.

Foundations of Parasitology, By GERALD D. SCHMIDT and LARRY S. ROBERTS. Blackwell Scientific: 1985. Pp. 775. Hbk. ISBN 0-8016-1385-6. 133-50.

Gastrointestinal Motility: The Integration of Physiological Mechanisms. By DAVID GRUNDY MTP Press:1985. Pp.183. ISBN 0-85200-894-5. £29-95.

The Genetics and History of Drosophila, Vol. 3d. M. ASHBURNER, H.L. CARSON and J.N. THOMPSON Jr. (cds), Academic:1985, Pp. 382, Hbk ISBN 0-12-064948-9, \$95.

Handbook of Marine Mammals. SAM H. RIDG-WAY and SirglCHARD HARRISON (eds). Academic: 1985. **?PF:362.** Hbk. ISBN 0-12-588503-2 564-50, E58-50.

Human Nature: Darwin's Views. By ALEXAN-DER ALLAND Jr. Columbia University Press; 1985. Pp. 242. 18BN 0-231-05898-5, \$25.

Introducing Immunology. By NORMAN STAINES, JONATHAN BROSTOFF and REITH JAMES, Gower: 1985, Pp. 59, Phk ISBN 0-906923-57-3, Phk FL 95.

Introduction to Bryology. By WILFRED B. SCHOFIELD, Macmillan, New York: 1985, Pp. 431, Hbk ISBN 0-02-949660-8, \$45

An Introduction to Ethology. By P.J.B. SLATER. Cambridge University Press;1985. Pp. 195. ISBN 0-52130266-8. Hbk £22.50, \$39,50; pbk £7.95, \$12.95.

Molecular Biology of Development, Vol. 1: Molecular Events. By A.A. NEYFAKH and M.Ya. TIMO-FEEVA. Plenum, USA/Nanka, USSR:1985, Pp.351. Hbk ISBN 0-306-413337. S95.

Mongoose Watch: A Family Observed. By ANNE RASE, John Murray 1985. Pp.298. ISBN 0-7195-1240-5-410-95.

Monoclonal Antibodies Against Bacteria, Vol. 1. ALBERTO J.L. MACARIO and EVERLY CONWAY DE MACARIO (eds). Academic:1985. Pp.320. ISBN 0-12-463001-4. \$45. £39.50.

Morphometrics in Evolutionary Biology. By F. BOOKSTEIN. B. CHERNOFF. R. ELDER. J. HUMPHRIES. G. SMITH and R. STRAUSS. The Academy of Natural Sciences of Philadelphia:1985. Pp.277. Hbk ISBN 0-910006-47-4; pbk ISBN 0-910006-48-2. Np.

Neurobiology: Molecular Biological Approaches to Understanding Neuronal Function and Development. PAUL O'LAGUE (ed.). Alan R. Liss:1985. Pp.212. Hbk ISBN 0-8451-2623-7. £52.

Nutrient Cycling in Tropical Forest Ecosystems. By CARL F. JORDAN. Wiley: 1985. Pp. 190. ISBN 0-471-90449-X. £13.95.

Pertussis Toxin. RONALD D. SEKURA, JOEL MOSS and MARTHA VAUGHAN (eds). Academic: 1985. Pp.255. Hbk ISBN 0-12-635480-4. \$34.50, £30:50.

Phospholipids in Nervous Tissues. By JOSEPH EICHBERG. Wiley:1985. Pp.386. ISBN 0-471-86430-7-f88-10.

The Platelets: Physiology and Pharmacology. GESINA L. LONGENECKER (ed.). Academic: 1985. Pp. 489, 15BN 0-12-455555-1. 865, £56.50.

Recognition and Regulation in Cell-Mediated Immunity. JAMES D. WATSON and JOHN MAR-BROOK (eds). Marel Dekker:1985. Pp. 480. ISBN 0-8247-7268-7. \$75.

Seed Ecology. By MICHAEL FENNER. Chapman & Hall:1985. Pp.151. ISBN 0-412-25930-3. Np.

Selected Topics from Neurochemistry. NEVILLE N. OSBORNE (ed.). Pergamon:1985. Pp. 534. ISBN 0-08-031994-7. £65, \$85.

Sensory Perception and Transduction in Aneural Organisms. GIULIANO COLOMBETTI, FRANCESCO LENCI and PILL-SOON SONG (eds). Plenum: 1985. Pp. 330. Hbk ISBN 0-306-42000-7. Np.

Sex and Repression in Savage Society, By BRONIS-LAW MALINOWSKI. University of Chicago Press: 1985, Pp.285. Pbk ISBN 0-226-50287-2. Pbk \$10.95.

The Thalamus. By EDWARD G. JONES. Plenum:1985. Pp. 935. ISBN 0-306-41856-8. Np.

Theories and Models in Cellular Transformation. L. SANTI and LUCIANO ZARDI (eds). Academic: 1985. Pp.179. ISBN 0-12-619080-1. \$25, £22.50.

The Tungara Frog. By MICHAEL J. RYAN. The University of Chicago Press:1985. Pp. 230. Hbk ISBN 0-226-73228-2; pbk ISBN 0-226-73229-0. Hbk £27.95; pbk £12.75.

Virus Structure and Assembly. SHERWOOD CASJENS (ed.). Jones and Bartlett, Boston:1985. Pp.295. Hbk ISBN 0-86720-044-8. Np.

The World's Whales: The Complete Illustrated Guide. By STANLEY M. MINASIAN, KENNETH C. BALCOMB III and LARRY FOSTER. W.W. Norton:1985. Pp.224. ISBN 0-89599-014-8. \$30, £25.

Psychology

Behaviour Analysis and Contemporary Psychology. C.F. LOWE, M. RICHELLE, D.E. BLACKMAN and C.M. BRADSHAW (eds). Lawrence Erlbaum Associates: 1985. Pp. 297. Hbk. ISBN 0-86377-025-8. F19 95

Current Issues in Clinical Psychology, Vol.2. ERIC KARAS (ed.). Plenum:1985, Pp.370, Hbk ISBN 0-306-42088-0, Np.

Epidemiology and Community Psychiatry: Psychiatry: The State of the Art, Vol.7. P. PICHOT, P. BERNER, R. WOLF and K. THAU (cds), Plentin: 1985, Pp.693, Hbk ISBN 0-306-41607-7. Np.

Evaluating Competencies: Forensic Assessments and Instruments. Perspectives in Law and Psychology, 7. By THOMAS GRISSO. Plenum: 1986. Pp. 404. Hbk ISBN 0-306-42126-7. Np.

The Handbook of Behavioral Group Therapy. DENNIS UPPER and STEVEN M. ROSS.

(cds), Plenum: 1985, Pp. 513, ISBN 0-306-41989-

0. Np. Health Psychology: A Psychobiological Perspective. By MICHAEL FEUERSTEIN, ELISE E. LABBE and ANDRZEJ R. KUCZMIERCZYK. Plenum: 1986. Pp. 511. Hbk ISBN 0-306-42037-6. Np.

History of Psychiatry, National Schools, Education and Transcultural Psychiatry, P. PICHOT et al. (eds.), Plenton: 1985, Pp. 744, ISBN 0-306-41608-5, Np.

Issues in Cognitive Modeling. By A.M. AIT-KEN-HEAD and J.M. SLACK. Lawrence Erlbaims: 1985, Pp. 349, ISBN 0-86377-030-4. Pbk 15, 95

The Nightmare: The Psychology and Biology of Terrifying Dreams. By ERNEST HARTMANN. Harper & Row 1986. Pp. 294. Hbk ISBN 0-465-05109-X.

The Psychoanalytic Movement. BY ERNEST GEL-LNER. Granada Publishing: 1985. Pp. 241, Pbk 1SBN 0-586-08436-3, £3.50.

Psycholinguistics. By ALAN GÁRNHAM. Methuen: 1985. Pp. 269. Pbk ISBN 0-416-36620-

Psychotherapeutic Change. An Alternative Approach to Meaning and Measurement. By ALVIN R. MAHRER. W.W. Norton:1986. Pp.208. Hbk ISBN 0-393-70007-0. £19.50, \$28.50.

Self-Psychology and the Humanities: Reflections on a New Psychoanalytic Approach. By HEINZ KOHUT. W.W. Norton: 1986. Pp. 290. Hbk ISBN 0-393-70000-3. £22, \$30.

Social Relationships and Cognitive Development. ROBERT A. HINDE. ANNE-NELLY PERRET-CLERMONT and JOAN STEVENSON-HINDE (eds). Oxford University Press: 1986. Pp., 384. Hhk ISBN 0-19-852157-3; pbk ISBN 0-19-852167-7. Hbk £37,50; pbk £19,50.

Surface Dyslexia: Neuropsychological and Cognitive Studies of Phonological Reading. K.E. PATTER-SON, R.C. MARSHALL and M. COLTHEART (eds). Lawrence Erlhaum Associates: 1985. Pp.544. 0-86377-026-6. Np.

Why Isn't Johnny Crying? Coping with Depression in Children. By DONALD'H. McKNEW Jr. LEON CYTRYN and HERBERT YAHRAES. Norton: 1986, Pp.187. Pbk ISBN 0-393-30240-7. £4.50. \$6.30.

General

Drinking Water Materials: Field Observations and Methods of Investigation. By D. SCHOENEN and H.F. SCHÖLER. Ellis Horwood;1985. Pp.195. Hbk ISBN 0-85312-929-0. £25.

Emile du Bois Reymond (1818–1986) — Anton Dohti (1840–1909). Briefwechsel. CHRISTIANE GROEBEN and KLAUS HIERHOLZER. Springer Verlag: 1985. Pp. 322. Pbk ISBN 3-540-15812-X. Np.

Evolving Hierarchical Systems. By STANLEY N. SALTHE. Columbia University Press: 1985. Pp. 343. ISBN 0-231-06016-5. \$30.

Fire. By JOHN W. LYONS. W.H. Freeman: 1985. Pp. 170. ISBN 0-7167-5010-4. £15.95.

Games Pets Play, or How Not to be Manipulated by Your Pet. By BRUCE FOGLE. Michael Joseph: 1986. Pp. 218. Hbk ISBN 0-7181-2674-2. £9.95.

The Harvey Lectures, 1983-1984. By RICHARD AXEL et al. Academic: 1985. Pp. 286. ISBN 0-12-312079-9. \$65, £56.50.

Hedges, Walls and Boundaries. By ROMOLA SHOWELL. Dryad Press Limited, London, UK: 1986. Pp.48. Hbk ISBN 0-8521-96245. £6.50.

How Nuclear Weapons Decisions are Made. SCILLA MCLEAN (ed.). Macmillan, in association with the Oxford Research Group:1986. Pp.264. Pbk ISBN 0-333-40583-8. £6.95.

Humanism and Anti-Humanism: Problems of Modern European Thought. By KATE SOPER. Http://doi.org/10.1009

Imposing Aid: Emergency Assistance to Refugees. By B.E. HARRELL-BOND: Oxford University Press:1985. Pp. 440. Pbk ISBN 0-19-261543-2. Hbk £15; pbk £2.50.

Influence of Modern Style of Life on Food Habits of Man. J.C. SOMOGYI and G. VARELA (eds). Karger: 1985. Pp.91. ISBN 3-8055-4152-X. DM 99, \$35.50.

An Introduction to Minimal Currents and Parametric Variational Problems. By ENRICO BOMBIERI. Harwood Academic Publishers:1985. Pp. 384. Pbk ISBN 3-7186-0299-7: \$25.

Islamic Metalwork in the Freer Gallery of Art. By ESIN ATIL, W.T. CHASE and PAUL JETT. Smithsonian Institution Press:1985. Pp.273. Pbk ISBN 0-87474-249-8. \$17.50.

Leviathan and the Air-Pump. Hobbes, Boyle and the Experimental Life. By STEVEN SHAPIN and SIMON SCHAFFER. Princeton University Press: 1986. Pp. 440. Hbk ISBN 0-691-08393-2. \$60.

The Management of Productivity and Technology in Manufacturing. PAUL R. KLEINDORFER (ed.). Plenum: 1985. Pp. 331. ISBN 0-306-42032-5. Np.

Mathematical Methods in Human Geography and Planning, By A.G. WILSON and R.J. BENNETT. Wiley:1985. Pp.411. Hbk ISBN 0-471-10521-X. £29.95.

Methodological and Statistical Advances in the Study of Individual Differences. CECIL R. REYNOLDS and VICTOR L. WILLSON (eds). Plenum: 1985. Pp. 472. Hbk ISBN 0-306-41962-9. Np.

The Mind Palace. By STEVE R. PECZENIK. Simon and Schuster:1985. Pp.335. Hbk ISBN 0-671-52433-X. \$16.95.

52433-X. 510.95.

The Origins of Logic: One to Two Years. By JONAS LANGER. Academic: 1985. Pp. 415. Hbk ISBN 0-12-436555-8. £65, \$75.

Pressures on the Countryside. By DERRICK GOLLAND. Dryad Press Limited, London, UK: 1986. Pp. 48. Hbk ISBN 0-8521-9625-3. £6.50.

Scientific Evidence for Dietary Targets in Europe. J.C. SOMOGYI and A. TRICHOPOULOU (eds). Karger:1986. Pp.162. Hbk ISBN 3-8055-4161-9. SwFr. 150, DM 180, \$64.

DIAMOND GENESIS

iastorationy completele

nature

NATURE VOL. 322 14 AUGUST 1986

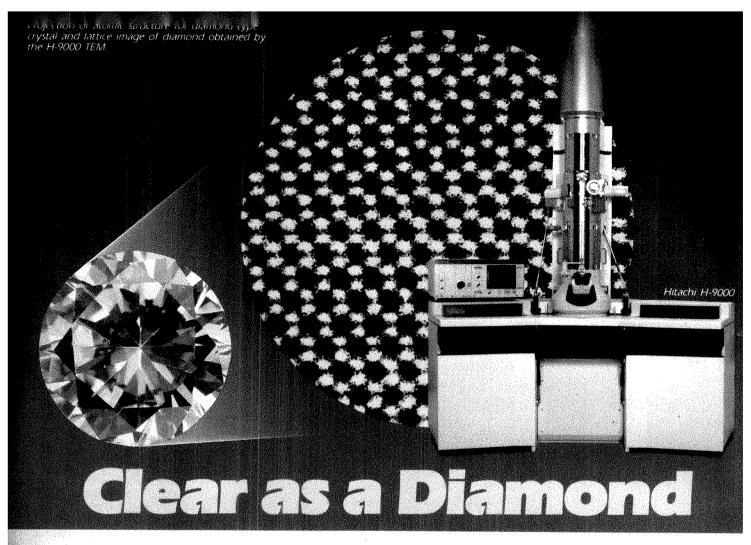

Pale-green clinopyroxene and deep-orange garnet crystals, found as tiny (~250 µm) inclusions in diamonds from the Premer mine, South Africa. These inclusions yield ages contemporaneous with the magmatism which brought the diamonds to the surface (see p.623), implying an origin for these diamonds which is related to their host magmas, and distinct from that of older olivine-bearing diamonds.

The Hitachi H-9000 300-kV TEM produces images with the stunning brilliance of a diamond.

The incredible penetration power and superb ultrahigh resolution of the Hitachi H-9000 300-kV transmission electron microscope has produced the world's first micrographs of the atomic structure of the diamond.

Dramatic Improvement Over Conventional 100-kV and 200-kV TEMs

Combining improved imaging resolution, a specimen penetration proportional to the electron velocity, an improved electron diffraction mode accuracy, and an improved spatial resolution for X-ray analysis, in which spread of beam penetration within a specimen is inversely proportional to the accelerating voltage, the Hitachi H-9000 TEM has produced stunningly clear micrographs of the diamond at the atomic level in remarkable detail.

This important achievement dramatically demonstrates the H-9000's ability to observe and analyze thicker specimens — a capability critical to the advancement of materials science, semiconductor technology, biomedical research, and other high-tech fields.

Compact Power

Based on Hitachi's extensive experience in million-volt microscopes, the H-9000 features a 10-stage acceleration system that provides ultrastable accelerating voltages of up to 300kV in an instrument of modest proportions. Enabling simple installation, use, and maintenance, the H-9000 easily fits in a normal-sized laboratory room, and operates just like a conventional 100-kV or 200-kV TEM.

Sophisticated Analytical Features

In addition to the conventional Be-window detector, a UTW detector may be mounted simultaneously, forming a dual EDX detection system. A special EELS using secondary aberration corrected three-dimensional focus spectrometry provides optimum analytical capability at 300kV. A TV monitor image intensifier system, SEM/STEM analytical applications, and a CBED fine probe add to the capabilities of the H-9000, one of the most powerful analytical microscopic systems available today.

GUIDE TO AUTHORS

Authors should be aware of the diversity of Nature's readership and should strive to be as widely under-

Review articles should be accessable to the whole results ership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose consciusions are of general interest or which represent suffstantial advances of understanding. The text should not exceed 3.000 words and six displayed items (illgures plus tables). The article should include an italie heading of about 50 words.

Letters to Nature are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was under taken and what the conclusions are

Matters arising are brief comments (up to 500 words) on articles and letters recently published in Nature The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted

Manuscripts may be submitted either to London or Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first

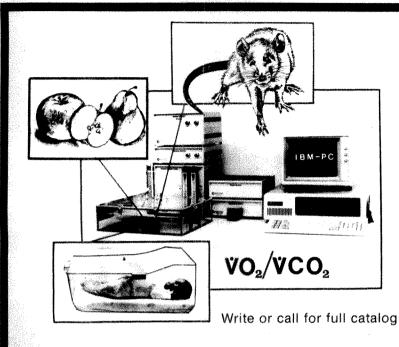

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the World List of Scientific Periodicals, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be effect. Reference to books should clearly indicate the pulslisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

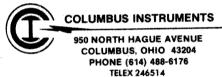

Important: Manuscripts or proofs sent by air courses should be declared as "manuscripts" and "value \$5" to prevent the imposition of Customs duty and Value Added Tax in the United Kingdom.

Requests for permission to reproduce material from Nature should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.

O₂ CONSUMPTION / CO₂ PRODUCTION "OXYMAX" COMPUTERIZED SYSTEMS

- ★ Utilized IBM-PC computer.
- ★ Prints and stores results on the disk in one minute intervals.
- ★ Monitors simultaneously 1 to 4 compartments (cages).
- ★ For animals, measures respiration rate and locomotor activity along with $\mathring{V}O_2/\mathring{V}CO_2$
- ★ Can easily be modified to suit variety of animal sizes.
- ★ High accuracy and stability. (better than 1%)
- ★ Twenty-four hours unattended operation.

Computer Graphics and Molecular Modeling

Edited by Mark Zoller, Cold Spring Harbor Laboratory; Robert Fletterick, University of California School of Medicine, San Francisco

COMPUTER GRAPHICS AND MOLECULAR MOD-ELING summarizes work presented at a December 1985 Cold Spring Harbor Laboratory Banbury Center meeting at which a diverse group of researchers addressed issues such as protein sequence homology, three-dimensional structure homology in proteins, molecular design of functional macromolecules, X-ray crystallography, hardware and software for displaying and analyzing three-dimensional macromolecules, and software for the analysis of the energetics and dynamics of proteins.

Molecular biologists, crystallographers, and computer specialists will find COMPUTER GRAPHICS AND MOLECULAR MODELING a useful collection of extended abstracts indicating directions for integrating the various approaches to the study of protein structure and function.

1986, 145 pp., illus., colorplates, appendix Paper \$29 ISBN 0-87969-193-X

nature

NATURE VOL. 322 J4 AUGUST 1986

A tale of two companies

The British government has made a muddle of its decision to prevent one electronics company from taking over another. It should pay more attention to what happens in the United States.

By an historical accident dating from the nineteenth century, Britain and the United States have in common not merely some usages of the same language, but also the existence of two public companies (corporations), one British and one American, that are called the General Electric Company. Both companies owe their origins to the demand, at the turn of this century, for machines for the generation, distribution and use of electric power. With the passage of time, both have become hugely successful and enormously diversified. Each, for example, has an interest in the manufacture of military aircraft, no doubt because the traditional manufacture of steam turbines for electricity generating sets provided a natural opening into the manufacture of jet engines. Inevitably, each has also an interest in consumer electronics.

The parallel between the British and the US companies has recently been even more striking; both have been seeking to grow by the acquisition of others. This is the spirit in which, earlier this year, GE of the United States merged with RCA Inc., itself a diversified conglomerate. It is also the spirit in which the British General Electric Company (GEC Ltd) had sought to merge with the smaller but still very substantial company called Plessey. The difference, between the United States and Britain, is that the British government has now used its anti-monopoly regulations to deny GEC the opportunity to pursue its commercial bid for Plessey.

Why should the British and US governments react so differently? Both governments are rightly concerned that companies should not become monopolists in their markets, charging their customers prices unrestrained by competition and serving the while as brakes on technical innovation. In the United States, the proposed acquisition of RCA by GE was formally studied by the US Department of Justice, which decided that the huge scale of the proposed merger was not in itself objectionable and that the fields in which the interests of GE and RCA most nearly coincide (defence and consumer electronics) are so competitively occupied by others that the merged company is unlikely to be a monopolist. In Britain, the proposed merger between GEC and Plessey was referred for consideration to the quasi-judicial Monopolies and Mergers Commission, which has the duty to consider the monopolistic risks of circumstances referred to it by the government, and whose conclusions may either be accepted (and then enforced) or, alternatively, may be rejected. On this occasion, the monopolies commission came out against the merger. The Secretary of State for Trade and Industry last week accepted this conclusion, the zeal with which his civil servants argued in the opposite direction when presenting their department's evidence to the commission notwithstanding.

Lessons

It will not be long before those concerned with this decision will be wishing they had behaved differently. The report of the monopolies commission, and the British government's ready acceptance of it, is a sign that people in Britain who should know better have not yet learned the lessons of the past few decades of industrial decline. The idea that GEC and Plessey should be merged is, ironically, itself a direct consequence of the policies of past and present governments towards telecommunications. Once upon a time, nearly two decades ago, the then nationalized telecommunications authority set about the development of digital electronic switching systems (called trendily "System X") by inviting manufacturers to belong to a joint "research committee" constituted so as to persuade them to help pay for the high cost of developing such a system by promising them a share of the business that would eventually result, both domestically and from export sales. In the event, that enterprise has been a cruel disappointment. Of the original group of manufacturers, only GEC and Plessey survive. System X compares reasonably well with other modern equipment, but has been much delayed and is unlikely to command the huge export markets once talked of.

Worse still, for the companies concerned, their once-cosy relationship with the monopoly customer for telecommunications equipment has been undermined by the decision, fully implemented only two years ago, that British Telecom should become a commercial company. Not surprisingly, this monopoly customer now says it does not wish to have to depend on the old ring of suppliers. Now it plans to order some switching gear from other than British companies.

Rationalization

Accordingly, it is generally agreed, even by the monopolies commission, that GEC and Plessey must do something to rationalize their interests in System X. Indeed, the proposal that one should buy the other appears to have arisen directly out of the abortive talks between them over the past few years. What the commission now suggests is either that one should sell its switching business to the other or that they should jointly set up a separate company to handle their combined interest in digital telecommunications. The commission's report (Cmnd 9867, HMSO £9.80) unfortunately says nothing of the obvious snags. Is either of the two companies likely permanently to opt out of a field of technical development of such manifest importance, and would it be in the British national interest if that could be arranged? Even the suggestion that these two independent companies should be forced into a joint venture under the banner of a third company has little to be said for it, given the well-known instability of shotgun marriages and the nearcertainty that both parties to such an enterprise intended merely to market a particular digital switching system would promptly (and sensibly) lose interest once a more attractive venture came along. If telecommunications were the only issue, the case for encouraging one company to buy the other would be irresistible.

So why should the argument have gone the other way? What seems most of all to have weighed with the monopolies commission, and eventually with the government, is the protest by the British Ministry of Defence that a merger of GEC and Plessey would give the combined company a virtual monopoly of the capacity to supply particular kinds of equipment, with the result that the ministry would not be able fully to implement its present policy of buying as much as possible of the defence equipment it needs only after companies working in the field have put in competitive tenders. But this argument is humbug.

The ministry is right to wish to buy its defence equipment as cheaply as possible, but is wrong to advance, for the purposes of a monopoly investigation, the argument that there have to be two potential British suppliers of everything it may choose to buy. The monopolies commission might just as sensibly have invited the defence ministry to follow British Telecom in listing overseas suppliers among those competing for its business.

This is the nub of the difficulty the British government has now created for itself. Although GEC is among the largest of British companies, it is tiny by the yardsticks of its direct competitors elsewhere, with annual sales roughly one sixth of the new combination of GE and RCA in the United States. Yet what the past few years have shown, specifically in the development of digital switching systems but generally, in electronics as a whole, is that the costs of launching new projects are invariably huge. Moreover, speed is of the essence; there are no prizes for being second. The point has probably now been reached at which only huge companies with long pockets can hope successfully to launch new projects that are technically interesting and likely to change the world in important and profitable ways. The sad history of System X shows the penalties of spending too little too late.

The British government, which for most of its spell in office has stuck to the principle that governments should not second-guess entrepreneurs, has on this occasion allowed itself to make industrial policy by default, by tamely accepting what the majority of the monopolies commission had to say (there is a dissenting minority report). The wisdom of this easy course will never be directly tested, for there may not now be a chance to tell what a slightly larger company than GEC might be able to accomplish by way of technical innovation. But there can be no doubt of its inequity; under British as distinct from US law, there is no way in which such decisions, however unfair they may be to shareholders of companies such as GEC, can be tested in the courts.

The moral in this sad tale is that all governments should take this opportunity to look again at their arrangements for regulating monopolies. In Britain, it is plainly an expensive luxury that companies are prevented from doing what makes economic sense for the sake of giving the defence procurement people the choice of several competitors for defence contracts; if that is what they believe they need, they should be prepared to throw the bidding open to all comers. In most European countries, there is an urgent need to ask how national legilation on monopolies can be squared with the general doctrine that trade flows freely across what used to be national frontiers. And to the extent that the United States now feels as much threatened by Japan as by the danger that its own companies might rig the domestic and overseas markets to their own advantage, there is a strong case for asking that the full rigours of the anti-trust legislation should be softened in the interests of the ultimate beneficiaries — those who buy the products of the new technology.

Nuclear regulation

The International Atomic Energy Agency has handled Chernobyl deftly. What next?

This is bound to be more than an unusually formative year for the International Atomic Energy Agency (IAEA) at Vienna; the next few weeks could tell just what the agency's future holds. This is the season at which the agency's board of governors holds its annual meeting, in recent years a more or less routine affair concerned with the difficulty of recruiting enough skilled inspectors to operate the safeguards system and with the constant anxiety about the budget (which amounted to \$87 million last year, modest for a UN agency). The difference this year is Chernobyl and its consequences, both immediate and for the future development of nuclear energy.

How has the agency, by instinct (and formal constitution) a sponsor of nuclear energy, handled the past few weeks? First, it has done well to ensure a reasonably regular and frequent flow of information about the damaged reactor at Chernobyl. After ten tense days from 26 April, pressure from the agency seems to have been instrumental to that end, while its constitution as an international agency appears to have made it acceptable to the Soviet authorities and other governments in Eastern Europe as a repository of information. More recently, the agency has done a valuable job in persuading member states to give some thought to the steps that need taking to keep each other alert to the risks of cross-border pollution by radioactive materials; in due course, these arrangements may have the force of a convention. Later this month, the agency hopes to go one important step further with the consultation that has been arranged at which the Soviet side says it will tell all about the accident at Chernobyl.

Sponsor of nuclear power though the agency may be, it plainly recognizes that its sponsorship will lead nowhere if ordinary people in its members states are left with the dark suspicion that each nuclear power station is potentially as much a source of catastrophe as was Chernobyl. That is the only sensible view to take. The agency's problem, in the years that lie ahead, will be to blend realism and optimism in a convincing way. That will be a formidable task.

Deeper pork barrels

Is the academic community in the United States too exercised by Congress's wayward ways?

For the past few years, the US Congress seems to have become an embarrassment to many in the academic community who are resentful of the notion that research funds should be distributed by congressional whim rather than by the more familiar techniques of judicious peer review and solemn committee discussion. Last year, Cornell University turned down the offer of a research grant it had not sought and in the process won the approval of those who believe that the award of money for research is a process far too serious to be left to the hunches of people whose only achievement is merely to have run successfully for public office. Most other recipients of these funds, which amount in total to rather more than \$10 million in any year, but probably less than \$50 million, have kept the money but have not advertised the fact. This year, in the rush to finish off the new tax bill and the budget for the financial year beginning in just six weeks, it is inevitable that many proposals for the support of specified research projects will finish up as amendments which are added almost surreptitiously to legislation making its way through the Congress for other purposes.

The US research community will do itself very little good if it takes too prim a view of these developments. Naturally, it would indeed be disastrous for the pattern of research in the United States if any but a small proportion of the funds available for research were to escape the standard system of scrutiny, or if the only means open to researchers for recruiting support for their work required, in the first instance, close personal acquaintance with an elected member of the Congress. But the sprinkling of research grants so far awarded from the pork barrel into which Congress from time to time dips hardly amounts to a substantial threat to the system as its stands. To the extent that most of the grants awarded in this informal way stem from the personal concern (however self-interested) of a congressman for a local academic institution, their frequency may even be regarded as a welcome sign that legislators are not as indifferent to the needs of the research community as they are sometimes said to be. Provided that the frequency of these grants does not get out of hand (in which case the spending agencies would no doubt decline to accept the instructions foisted upon them), there is a case for regarding them as a welcome way of bridging gaps in the orthodox system. Is not plurality still a benefit?

NASA

US space station heads for deep freeze

Washington

BUDGET pressures on the National Aeronautics and Space Administration (NASA), together with management changes recommended by the Rogers commission and astronauts' heightened concern about safety, are forcing a major rethink of the agency's plan to build a habitable space station by 1994. NASA Administrator James Fletcher has ordered a thorough re-evaluation of current plans to take account of questions raised both by astronauts and by members of Congress sceptical of the feasibility of the dual-keel design announced in April.

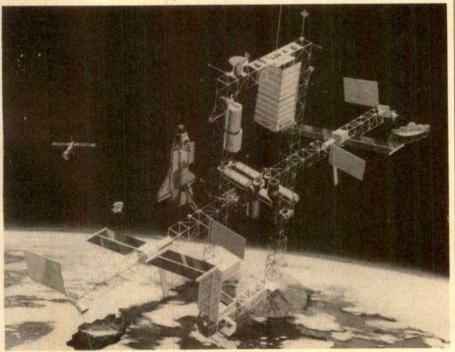

Worries about safety and feasibility have become enmired in a political row over NASA's plan to transfer development of the station's crew modules from Johnson Space Center in Texas to Marshall Space Flight Center in Alabama; much of the criticism of the present design has come from Johnson. The subcommittee in the House of Representatives that oversees NASA has directed the agency to delay implementation of Fletcher's proposals, and congressional representatives from Texas queued up in Congress last week to lambast the new management plan and to demand greater consultation.

The astronauts' primary concerns are that the current design includes no provision for an escape system and that construction will require too much extravehicular activity by astronauts. A simpler one-keel structure could, it is argued, be

built at less risk. Astronaut Gordon Fullerton, in a briefing paper for NASA officials, also said that morale on the space station programme is poor and that there is concern that NASA is misrepresenting what it can do to Congress. Fullerton called for development of a new heavy lift vehicle in conjunction with the Department of Defense that would be used to lift the core components on the space station. A radical reappraisal of the space station has also been called for by Senator Spark Matsunaga (Democrat, Hawaii), who favours separate government and commercial stations with different design objectives.

NASA officials say that although reviews of alternative construction plans are in progress, the basic dual-keel design formally proposed to Congress last April still stands. Provision of an escape module or a "safe haven", and a revised construction plan that would allow for earlier use of the space station, are among the options being studied. But Fletcher told Congress last week that the current design could be built only if a fourth shuttle orbiter to replace the Challenger is built. The administration should soon announce how a fourth shuttle would be paid for.

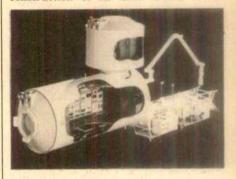

The extent of European participation in the space station is also still far from clear. The European Space Agency (ESA) is adamant that the permanently attached pressurized module for which preliminary design studies were agreed on 1 August

Japanese space plans go ahead

Tokyo

Despite uncertainties over the future of the US space station, Japan's Space Activities Commission has just released a report recommending continued "positive" participation. Over the past two fiscal years, Y5,500 million (\$36 million) has been allotted to the design of an experimental space module (above) to be attached to the space station, and the report recommends that construction of its main frame should

begin in 1989 with a view to launch in 1994.

The module will consist of a pressurized cabin ten metres long for use in experiments on new materials under gravity-free conditions, an exposed service platform equipped with a manipulator and a storage cabin. One or two astronauts will man the station and the report urges the government to begin training in earnest. The estimated cost of the module is Y350,000 million (\$2,300 million). David Swinbanks

will be used mainly for materials research, where profitable spin-off technologies are most likely to emerge. But a congressional committee that approves NASA's budget recently recommended that \$150 million of the \$410 million sought by the agency for space station development next year should be reserved until certain conditions had been met, among them that ESA's pressurized module will be restricted to life science research.

The 1 August agreement indicates that ESA will also conduct preliminary design work on a man-tended free-flying pressurized module that could dock on the space station, as well as a polar orbiting platform. In return, NASA has agreed that it will study the man-tended free-flyer module jointly with ESA. This is essentially a compromise to allow ESA to continue work on the free flyer, which it has favoured all along as its primary contribution but about which NASA is unenthusiastic. The interim agreement covers only preliminary design.

All concerned acknowledge that the NASA/ESA agreement has merely allowed work to continue and has not resolved fundamental differences of approach between the two sides.

Tim Beardsley

European Commission

Framework to be scaled down

Ambitious plans for a major expansion of European research and development are cut back by 30 per cent in the latest proposals from the European Commission. The European "framework programme" was to have cost in excess of

10,000 million ECU (over £15,000 million). But European research ministers, meeting in June, protested when they saw the budget was more than double the cost of research at present being sponsored by the Commission.

Commission officials had hoped for better progress on the Common Agricultural Policy (CAP), which absorbs more than two-thirds of total Commission spending in farmers' subsidies. If CAP had been trimmed, that could have left room for a larger research programme, now representing only 2 per cent of national research and development budgets. Instead, CAP has grown, the Commission budget has been pushed to its legal ceiling (1.4 per cent of member states' value added tax receipts), and smaller programmes have little chance of gaining extra funds.

Commission research, mostly performed in national, university or industrial laboratories, is strongest in energy (including nuclear fission safety research and fusion), the environment, information and communications technologies, biotechnology (particularly in relation to agricultural change and development), new materials, optical computing and technologies thought likely to revive old industries. Its objective is to unite European research groups on long-term projects and reduce duplication in national programmes. The framework programme is designed to set priorities for the next five years. Two years ago, when planning began, major expansion seemed both politically and financially possible. Now that CAP has eaten the cupboard bare, the Commission's research directorate must hope that increasing political interest in technological cooperation in Europe will generate support. There is plenty of competition, however, from independent projects such as Eureka aimed at stimulating Europe's hightechnology industries.

The new price-tag for the framework programme is 7,735 million ECU. The adjustments have been made to balance the differing national interests expressed at the last research council meeting: West Germany is reluctant to go into joint telecommunications research, where its principal company, Siemens, feels it has more to lose than to gain, while the British insist on continous programme assessment by outside experts.

Newer activities, such as information technology for the disabled, where the Commission has less experience, are also being cut back. A programme for research on "intelligent transport", involving advanced computers and communications in road vehicles has been cut because of strong overlap with a Eureka programme. New technologies for old industries are also out of favour. But energy research sees a slight increase in response to the

Chernobyl disaster. The whole of the Commission's nuclear fission research programme, much of it at the Commission's own Ispra laboratory in northern Italy, is now concerned with nuclear safety.

Will member states support the new proposals for the programme? Britain, whose technology minister Mr Geoffrey Pattie will be influential as he chairs the council of research ministers until the end of this year, believes there is room for an increase in total research spending, but not such a substantial one as the Commission is requesting, even in its revised budget. Commission officials certainly believe the larger member states, which pay most of the Commission's bills, are going to be reluctant, but will argue that everybody's long-term interests will be served by improving European cooperation in this area. Britain, however, with its reseach community in revolt at low levels of support at home, will be nervous about the impact of increased international spending on its national research budgets, a matter which is not entirely in Pattie's control. But with the Commission's final proposals now in the hands of national governments, real negotiation can begin.

Robert Walgate

Israeli science

Medical schools seek US students

Rehavot

US MEDICAL students at Tel Aviv University pay tuition fees of \$15,000 a year, a lot more than their Israeli counterparts, who pay only \$900 (a remarkably low sum decided on by the government). Yet there are far more US applicants for the programme in Tel Aviv than can be accepted. says Yehuda Bar-Shaul, rector of the university. That, he says, is because "the special English-language course at Tel Aviv is not like those of the dubious 'offshore universities' which many American students attend". The Tel Aviv institution has the status of a New York state medical school, and participants in the course who come from New York have more than 40 per cent of their tuition paid for by the state. Moreover, after graduation, the students do their residency in New York hospitals, "and the very best ones at that", the rector adds with pride.

Each year, Tel Aviv University's Sackler Medical School takes in some 60 students from the United States and about 80 from Israel. The US intake causes resentment among Israelis whose applications are rejected and who must therefore go to Italy or Rumania in order to study medicine, but, Ben-Shaul says, there is no justification for such resentment. "Even if this special programme were abolished", he declares, "we would not accept more local students because the 300 new doctors who graduate each year from the country's four medical schools are more than sufficient to meet Israel's needs."

The example set by Tel Aviv University over the past six years is to be copied by two other major institutions. A few weeks ago, the Haifa Technion decided in principle to begin a similar scheme at its own medical school. But Technion officials speak of fulfilling a Zionist mission, since most of those who would come to study in Haifa are likely to be Jews (as is the case in Tel Aviv). Officials readily admit that they also see the course as a potential source of income for the financially troubled Technion, which will be able to accept overseas students and their tuition fees without investing money in new facilities.

A similar scheme is on the agenda at the newly established Korat School of Veterinary Medicine of the Hebrew University. Its director, Professor Kalman Perk, expects an annual intake of 30 students, half Israeli and half foreign. But the programme will begin only in two years' time, after the opening of a veterinary hospital near the campus and after the first veterinary school class has graduated.

Unlike Tel Aviv University and Technion, overseas participants in the Hebrew University scheme will be expected, after the first year, to attend regular Hebrewlanguage classes.

Nechemia Meyers

Strategic Defense Initiative

Japan ready to participate

Tokyo

BUOYED by its landslide victory in the last Japanese election, the Nakasone administration is galloping to join the US Strategic Defense Initiative (SDI). The last barrier to participation, an all-party resolution banning the militarization of space, has been brushed aside and Japan is expected to decide to join the SDI research programme by the beginning of September. But there is less enthusiasm among those who will actually carry out the research.

In March last year, Mr Caspar Weinberger, US Secretary of Defense, formally invited Japan as well as other allies to participate in SDI. Since then, three Japanese delegations have been dispatched to the United States, the last of which, after its visit in April, strongly recommended participation on the grounds that SDI research would greatly benefit Japanese industry (see *Nature 321*, 5; 1986).

Since the July general election, two cabinet-level meetings on SDI have been held and several key decisions have been made. First, all patent rights to technology developed through SDI research will pass to the United States, although Japan will try to work out an agreement to ensure the return of technology to Japan. Without such a provision, the prime incentive for Japan's private industry to take part would be lost, as the main benefits for Japan are seen to lie in commercial spinoffs from SDI.

Second, although most research will be carried out by private enterprise, government agencies will be allowed to join the research effort, and secrecy will be maintained under the existing Secrets Protection Law. Finally, the six cabinet ministers, at their meeting last week, concluded that participation in the research phase of SDI would not violate a 1969 all-party Diet resolution banning military use of space. Defence-related issues usually provoke heated debate in Japan, and last week's cabinet decision would normally raise a storm. But opposition parties have remained remarkably silent on SDI following their crushing election defeat.

Dissent within Prime Minister Yasuhiro Nakasone's own Liberal Democratic Party (LDP) has also failed to materialize. Former Foreign Minister Shintaro Abe, a contender for the LDP leadership, is known to be cool towards SDI, but in his new post as chairman of the LDP executive council he no longer has a direct say in SDI and his successor at the Foreign Ministry, Tadashi Kuranari, is a close political ally of Nakasone. Nakasone himself has made no secret of his enthusiasm for SDI since he first discussed the issue with President Reagan last year, and a decision to go ahead would no doubt

strengthen the friendship between the US president and the Japanese prime minister.

Private industry's enthusiasm for SDI is more guarded. There are fears that it could merely end up being exploited, without enjoying the "fruits" of the research, and the decision to transfer patent rights to the United States will do little to allay such concern.

Although government research agencies

will also be able to participate in the SDI programme, there may be a lack of scientists willing to carry out the research. Nearly 5,000 Japanese scientists have signed petitions against SDI, including more than 1,600 at the national science research laboratories in Tsukuba, the very laboratories at which government SDI research is likely to be carried out. The scientists' chief concern seems to be that their research would be restricted as "military secrets", but they also fear an arms race in space and the increased dangers of nuclear war.

David Swinbanks

Environmental pollution

Pushing for a new clean-up law

Washington

AFTER languishing in legislative limbo, the US Comprehensive Environmental Response, Compensation and Liability Act, better known as the Superfund, is on the road to reauthorization. A conference committee last month completed the task of reconciling differences in new authorizing legislation already passed by the House of Representatives and the Senate.

Congress established Superfund in 1980 to clean up hazardous waste sites created before the passage of legislation regulat-

ing the dumping of such wastes. Superfund's first five-year authorizing legislation expired last October. The Environmental Protection Agency (EPA), responsible for Superfund clean-ups, has kept the programme going with residual funds and stop-gap appropriations from Congress. In the final version of the reauthorizing legislation, Superfund is authorized to receive \$9,000 million over the next five years, compared with \$1,600 million called for in the 1980 legislation.

One major obstacle to the implementation of Superfund is the issue of who will foot the bill for the clean-ups. The primary reason Congress failed to reauthorize Superfund when it expired last fall was an inability to come to terms with this issue. The Congress is in the process of working outa complete overhaul of the United States' tax code. So far, the issue of new

taxes to fund Superfund has not been taken up, and the issue is a divisive one. The petrochemical industry has claimed that paying the entire cost for clean-ups could be devastating for the industry's international competitiveness. One alternative is a value-added tax.

Under the new statutes, a timetable will be established for clean-ups to prod EPA to move more aggressively than it has in the past. Over the next four years, EPA will review some 23,000 potential Superfund sites around the country, with some 2,000 sites likely to be added to the 888 at present on EPA's National Priority List. Federal clean-up standards, absent from the original legislation, appear now, along with a provision that allows state standards to apply if they are more stringent.

Partly in response to the chemical plant disaster in Bhopal, India in 1984 (see Nature 312, 581; 1984), companies either using or creating toxic chemicals in manufacturing processes must inform local jurisdictions of their activities. This community "right-to-know" database could become a boon for epidemiologists if it is established as planned, providing information about environmental hazards. The new rules also require the Department of Health and Human Services to compile a toxicology profile on the commonest chemicals at Superfund clear-up sites.

Some critics of the new bill are concerned that issues of corporate liability have still not been adequately dealt with. Others say it does not go far enough to solving the problems caused by hazardous waste sites. A report by the Office of Technology Assessment (OTA) suggested that it would cost closer to \$100,000 million to clean up all the dump sites that could be eligible for Superfund action. OTA's Joel Hirschhorn says that for the first time funds will be available for developing new clean-up technologies, but otherwise sees no major improvement in the Superfund law. "It's one thing to throw money at a problem", says Hirschhorn, "and another to solve the problem."

Joseph Palca

Computer models

Cooperation on new molecules

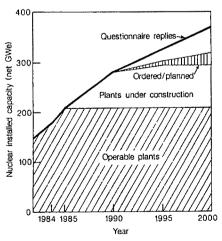

Washington

COMPUTER models are becoming increasingly popular for designing new molecules. But all such efforts face a fundamental problem: what parameters and potential-energy equations should be used in estimating the final energy state and geometry of a novel molecule? A recently formed consortium has set itself the ambitious task of supplying those parameters and equations. A successful outcome will mean model-builders will sleep easier, confident that their new creations will behave in nature the way they do on a computer screen.

The new three-year project is headed by Biosym Technologies, Inc., a company based in San Diego specializing in software for computer-assisted molecular design (CAMD). Each year, consortium members will contribute money and manpower: \$30,000 in cash support and six months of personnel time from a doctoral-level chemist. In return, consortium members have a say in the direction the

Nuclear forecast

AMID Chernobyl gloom, the Nuclear Energy Agency of the Organisation for Economic Cooperation and Development (OECD) is still presenting an optimistic picture of the growth of nuclear power worldwide. In 1985, there was a 19.2 per cent increase in nuclear electricity production, the largest increase since 1977. Twenty-one per cent of electricity generated in the OECD countries comes from nuclear power stations, ahead of hydro-

thermal and geothermal (20 per cent) and oil and gas (17 per cent) but behind coal (42 per cent). Forecasts to the end of the century shown in the graph were prepared from questionnaires returned by member countries. The highest forecast includes power stations not yet at the planning stage, where worries over safety may have their effect.

project takes, as well as gaining first access to the new database and any software tools that are developed. Companies participating in the consortium are Abbot Laboratories, Cray Research, E.I. du Pont de Nemours, Merck Sharp and Dohme Research Laboratories, Monsanto, Rohm & Haas and the Upjohn Company.

For certain classes of molecules, such as polypeptides and nucleic acids, these energy functions, known as force-field functions, have been fairly well approximated. The parameters are derived not only from bond energies, but from non-bonded molecular interactions as well. Peter Kollman, professor of pharmaceutical chemistry at the University of California, San Francisco, is the author of one widely used set of these functions. But Kollman says that, when looking beyond well-characterized classes of molecules, the applicability of the force-field functions becomes uncertain.

As an example, the van der Waals forcesbetween molecules in two classes of compounds may be similar, but the electrostatic charges may differ, forcing a model-builder to make assumptions about the best way to alter the force-field equations. The consortium hopes to develop a more generally applicable set of parameters and equations.

Biosym's chief scientific officer, Arnold Hagler, has also developed a well-known set of force-field equations. Hagler's plan is to use both empirical data gathered from existing literature and research done by consortium members, as well as quantum mechanics calculations, to develop a "second generation database of potential energy surfaces for organic, pharmacological and other biomolecules".

While most consortium members are also fierce competitors in the market-place, Upjohn's director of computational chemistry, Gerry Maggiora, explains that it will be to everyone's advantage to have a good set of potential energy functions. Upjohn is heavily involved in CAMD, one focus of which is developing inhibitors of renin for use as antihypertensive agents. As the three-dimensional structure of renin has not yet been worked out, Upjohn and others have turned to related compounds such as aspartyl proteinases to study molecules that will bind to renin's active site.

John Wendoloski of du Pont says companies should probably have put more money and effort into joint developments of force-field functions in the past. Although there is nearly uniform agreement that Biosym has undertaken a potentially useful task, there are those who doubt that a general set of force-field functions can be developed at present. Cyrus Levinthal of Columbia University, who is developing a special application computer with Brookhaven National Laboratory for computing interacting forces between molecules, says it is not clear whether sufficient empirical data exist to generate appropriate parameters. That sentiment is echoed by Kollman, as well as by John McAlister, director of research for Tripos Associates, another software company also working on the force-field problem. Even consortium members confess that hoping for a "second generation" database may be optimistic, but Abbot's Jonathan Greer says a better set of parameters than those currently available will be welcome. Joseph Palca

Return of tamarins proves expensive

Tokye

THE World Wildlife Fund has agreed to an unprecedented payment of about 10 million yen (\$65,000) to ensure that ten goldenheaded lion tamarins illegally imported to Japan three years ago return home to Brazil, according to the Japanese Foreign Ministry. Despite the acute embarrassment the illegal import of these rare primates has brought to Japan, the Japanese government is making no move to introduce legislation to prevent a repetition of such incidents, and has failed to provide funds for the safe return of the animals.

The weakness of Japan's laws has been quickly spotted by the yakuza, Japan's own mafia. Just a few weeks ago, they put a black tamarin on sale on the street outside a police station at Tokyo's Shinjuku station. Their sales point, capitalizing on media attention to the smuggling of endangered species, was that the tamarin had been brought in illegally from Brazil. No action was taken against them.

The lion tamarins, trade in which is banned under the Washington Convention on International Trade in Endangered Species, to which Japan is a signatory, were brought into Japan in 1983 with false import documents (see *Nature* 318, 200; 1985). The infringement was spotted by the World Wildlife Fund's TRAFFIC office. But, having got the monkeys past customs, the importers were free from prosecution as there is no domestic legislation to back up the terms of the convention.

Only constant lobbying by the World Wildlife Fund and international protests forced the government to take action. But it has no intention of paying the bill. According to the Foreign Ministry, the monkeys will be shipped to São Paulo Zoo in mid-September at a cost of 15 million yen, two-thirds of which will be paid by the World Wildlife Fund. The remaining one-third will come from the importer and keepers of the tamarins. David Swinbanks

Seismic monitoring

Station goes with a bang

THE Soviet-US seismic monitoring expedition to Karkaralinsk in Kazakhstan is essentially a confidence-building exercise aimed at showing it is possible to detect infringements of any future nuclear testban treaty, according to Oleg Stolyarov, a laboratory head from the Schmidt Institute of Earth Physics of the Soviet Academy of Sciences.

The expedition has been a unique cooperative venture that has allowed a team of US scientists to set up a seismic monitoring station in the Soviet Union. The Soviet side will reciprocate later and help to set up a station in Nevada. But the US government has not been involved: the

agreement is between the National Resources Defense Council, a private environmental group, and the Soviet Academy of Sciences (see *Nature* 321, 638; 1986).

Stolyarov, who has been acting as spokesman for the Soviet side, maintains that all the scientists on the expedition agree that seismic tremors can be monitored with sufficient accuracy to detect nuclear tests. The real purpose of the exercise, he maintains, is to convince the US authorities, who would prefer not to believe it.

Since the US participants do not have government backing, Stolyarov may have assumed that the government was hostile to the project. Other difficulties may have helped confirm this impression. As Co-Com regulations forbid the export of Western state-of-the-art technology to the Soviet bloc, the US equipment taken to Karkaralinsk was somewhat outmoded.

In the event, the Americans working at Karkaralinsk, a geological freak area where outcrops of bedrocks that are highly conductive to vibrations make it a natural seismic observation site, obtained excellent signals from nuclear blasts in Nevada.

Despite the political tensions generated by US reluctance to follow the Soviet example of declaring a nuclear moratorium, the two teams are said by Stolyarov to have "worked hard in a friendly way . . . brought together by a noble purpose".

Vera Rich

Ariane ride for Indian satellite

Bangalore

THE Ariane launch vehicle of the European Space Agency (ESA) will launch India's multi-purpose domestic satellite INSAT-1C in early 1988 according to an agreement signed between the Indian Space Department and Paris-based Arianespace. This agreement brings to an end uncertainty over the launching of INSAT-1C, originally planned for the space shuttle (see *Nature* 322, 198; 1986).

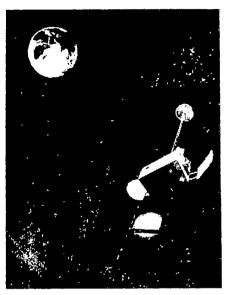

The INSAT spacecraft, described as the first civilian geostationary satellite to combine telecommunications, direct television broadcasting and meteorological observation tasks, are being built by the Ford Aerospace Communications Corporation (FACC) of Palo Alto, California, under a contract from the Indian Space Department.

With a launch weight of 1,180 kg, INSAT-1C is similar in configuration and performance to INSAT-1B, now in orbit. INSAT-1A, the first in the series, was launched in April 1982 but was switched off six months after its launch following a series of malfunctions. INSAT-1B went up in August 1983 and is running smoothly. All the spacecraft are designed for seven years active life in orbit. Successful launch of INSAT-1C will complete plans to have one operational satellite and one spare in orbit. INSAT-1D is expected to be launched in late 1988 or early 1989.

According to Professor U. R. Rao, secretary of the Indian Space Department, Arianespace offered the only competitive option after the shuttle failure had been followed by problems with the US conventional launcher, the Delta rocket. He said that the European launching system is as

good as the US system although it is a little costlier at US \$33 million. "But the French have gone out of their way to accommodate us", he said.

Frederic d'Allest, chairman of Arianespace, and Rao hailed the agreement as a

milestone in the long-standing and steadily growing cooperation in the field of space between India and Europe in general and France in particular. They are confident of further expansion of Indo-French cooperation in other areas such as remote sensing, satellite-aided search and rescue for the benefit of both countries.

Meanwhile, India is busy designing the second-generation INSAT spacecraft which will be built and launched in India. A liquid oxygen/liquid hydrogen launcher is being developed. Radhakrishna Rao

Doing things the all-American way

Washington

A BILL that would limit European and Japanese participation in the US Strategic Defense Initiative (SDI) has passed the Senate, and will be acted on by the House of Representatives this week. In a rare Saturday session, the Senate adopted an amendment, sponsored by Senator John Glenn (Democrat, Ohio), to the defence authorization bill that would prohibit the SDI office from signing contracts with foreign companies unless the Secretary of Defense certified that the work could not be performed in the United States. The amendment does not cover work subcontracted to companies outside the United States

In the House of Representatives, a similar amendment, sponsored by Representative Les AuCoin (Democrat, Oregon), would place a size limit of \$100,000 on SDI contracts with non-US companies. AuCoin's amendment does not permit ex-

ceptions. The House amendment is intended both to provide additional jobs for US workers and to prevent the Reagan administration from buying support for SDI from US allies with fat research contracts. It was impossible earlier this week to estimate the amendment's chances of success.

The Federation of American Scientists estimates that foreign SDI contracts at present amount to \$75 million. Although this represents only a small fraction of SDI's 1986 budget of \$3,050 million, some countries clearly hope for a much larger role in the project (see *Nature*, 322, 300; 1986).

The version of the defence authorisation bill passed by the Senate would limit spending on SDI to \$3,950 million, well below the administration's \$5,400 million budget request. That figure is likely to be trimmed even further in the House of Representatives' version.

Chernobyl accident

Reactor design not perfect

ACADEMICIAN Vitalii Legasov, a deputy director of the Kurchatov Nuclear Energy Institute, last week said that the design of the RBMK reactor was partially to blame for the Chernobyl disaster. The official Soviet viewpoint, embodied in a Politburo statement last month, was that human "irresponsibility" and "lack of labour discipline" was the cause. Workers at the power station, the Politburo said, had carried out unauthorized experiments on the Number 4 reactor, when it was undergoing a routine shutdown.

Although he did not disagree with the accident scenario, Legasov added some important details. In an interview for Japanese television, he said that the workers had not only carried out the "experiment" without the appropriate experts being present, they had also committed the "unbelievable" error of "keeping the emergency cooling system out of operation".

The experiment, he said, was intended to ascertain how long a power supply (for operating the reactor's own housekeeping functions) could be maintained after switching to the standby diesel generators. Such an experiment, he maintained, should have been carried out only with the reactor completely shut down and steam generation stopped. This account is compatible with the speculations of Western experts (see Nature 322, 399; 1986), that attempts to draw energy from the reactor in these conditions, well below the designed power range for the RBMK, produced steam voids within the cooling system, which caused power surges that

Guatemala accused of political killings

Washington

THE American Association for the Advancement of Science (AAAS) has submitted to President Vinicio Cerezo of Guatemala a grim catalogue of more than 200 political killings, "disappearances" and arbitrary detentions of Guatemalan academics and students between 1980 and 1985. Most are believed to have been killed with the approval or the tolerance of the military governments that ruled Guatemala between 1978 and last January.

The reports prepared by AAAS's commission scientific freedom and responsibility, urges President Cerezo, a civilian, to investigate the cases and to allow families to seek judicial redress. Most of the cases describe scientific and medical professionals who were shot or abducted by unidentified men. Estimates of the total number of political killings in Guatemala over the past 15 years range up to 100,000.

After AAAS presented a similar report to the new civilian government of Argen-

tina in 1984 detailing disappearances of 55 Argentinian scientists, the Argentine government requested forensic science assistance from AAAS to investigate the cases. Cerezo has pledged to foster greater respect for human rights and to reform the national police and security forces, but those in the military responsible for unlawful killings cannot be brought to justice until an amnesty declared by the outgoing military government is repealed. It is not clear whether Cerezo will be able or willing to repeal the amnesty.

Plans for an independent human rights commission on Guatemala with international representation have so far come to nothing, but the government has indicated that it may be willing to appoint a special ombudsman to investigate allegations of human rights abuses. In the meantime, one judge has been appointed to hear 1,400 writs of habeas corpus submitted by Grupo de Apoya Mutuo, a local human rights group.

could not be controlled by the slow-moving control rods of this type of reactor.

Where Legasov differs from the official Soviet viewpoint is in maintaining that not only were the "experimenting" workers at fault, but also the design team, who should have foreseen these events.

For some time, Legasov has been suggesting that the explanation of the Chernobyl disaster would be a complex one. Interviewed last month for the Soviet journal *New Times*, he described it as a "scarcely probable thing . . . a combination of several events, each of them scarcely probable either". The idea that the designers should be able to predict accidents is not entirely new to the Chernobyl coverage; interviewed by the Mos-

cow weekly Literaturnaya Gazeta in June, Academician Boris Semenov, deputy chairman of the State Committee for the Use of Atomic Energy, said that the safety systems at Chernobyl were sufficient to prevent any escape of radioactive material in even the worst scenario foreseen by the designers — clearly implying that some possibilities had been overlooked.

By placing the responsibility on the Chernobyl workers, the Politburo statement implicitly exonerated the RBMK design, which is one of the two basic types used in the current Soviet nuclear power programme. During the past few weeks, official statements have made it clear that there are no plans to phase out or close down RBMK-powered stations in the immediate future, although there have been some exhortations to the scientists to produce a "new, safer" generation of nuclear reactors as soon as possible. A need to express government confidence in the RBMK may well lie behind the appointment to the new post of All-Union Minister of Nuclear Energy of Nikolai Lukonin, formerly director of the RBMKpower stations at Leningrad (1976-83) and Ignalina, near Vilnius (1983-86). Behind the scenes, however, the government and party leadership may be less happy with the design. One of the four top officials dismissed in July as a result of the official inquiry into the accident was Ivan Emelyanov, who some 20 years ago was head of the design team that produced the RBMK. Retraining programmes for the staff of nuclear power stations, including computer simulation of accidents and emergencies, are being introduced, and the siting of some projected power-station is now said to be under review.

Japan's sunset export industry

Tokvo

THERE is nothing like an old solution for a new problem. For years, Japan's Ministry of International Trade and Industry (MITI) has been exhorting industry to export, export and export some more. Now the nation has a new problem: with the Japanese the longest-lived people in the world, there are soon going to be far too many old people. The MITI solution — export them!

Under the "Silver Columbia '92" plan, Japan's old-age pensioners will be able to set off to foreign lands where they can live in peace and comfort supported by an everrising yen. Life back home would be much harder, given the poor provision for pensions and the unwillingness of the government to take on any new financial commitments.

MITI foresees the establishment of

Japanese villages of around 1,000 people each, with construction beginning in 1990. Of course, a few problems remain. Next year, MITI and the Japan External Trade Organization will work out where the villages should be and ways of tackling language barriers and supplying Japanese food. Countries will be selected in the light of climate, law and order, medical services, housing and popular sentiment towards Japan.

Although the Japanese government would negotiate with the prospective host country, MITI wants the private sector to run the scheme. It is not yet clear how foreign governments will react. Will they see it as a welcome transfer of "intellectual property" or just another case of "dumping"? Could a trade develop? And would Japan be happy to import a few pensioners from elsewhere?

Hubble space telescope

Every delay has a silver lining

Baltimore, Maryland

THAT the launch of the Hubble Space Telescope seems likely to be delayed until 1989 may yet turn out to be a blessing in disguise. Many project scientists believe that the three-year delay, caused by the Challenger space shuttle accident, will give time to make the telescope more

Riccardo Giaccon

effective – provided the National Aeronautics and Space Administration (NASA) can avoid making major cutbacks.

Samuel Keller, deputy associate administrator of NASA's Office of Space Science and Applications, says the agency hopes to avoid redundancies at the Space Telescope Science Institute (STSI) in Baltimore, but that a 10–20 per cent fall in staff numbers is likely, due to natural wastage. No new staff are being taken on. At Marshall Space Flight Center in Alabama, staff reductions have taken effect. As Keller points out, NASA has to comply with levels of funding and directives imposed by Congress.

The telescope's large size (43 ft) and weight (around 24,000 lb) mean that only the shuttle could put it into space. NASA recently announced that the shuttle will not fly before 1988, but Dr Riccardo Giacconi, director of STSI, believes it "still reasonable" to hope for launch during 1988. Giacconi thinks the telescope could be the third to the fifth payload in line once flights resume. The first will probably be military, and the second a tracking and data relay satellite to replace that lost with Challenger (one such satellite is now in operation for dual military and civilian use, but at least two are needed for safe control of the telescope).

Keeping the telescope waiting is not likely to cause problems. But the delay will necessarily mean large cost increases at Lockheed Missiles and Space Corporation in California, where about 150 people are testing the telescope. NASA has considered stopping work until close to launch, but it would still be necessary to keep an experienced engineering team together for pre-flight tests. Giacconi now thinks he has NASA's support for keeping the telescope accessible for testing until launch, but major reductions in the

Lockheed workforce are still likely.

There is clearly still much to do. The main controlling system, the space operations ground system, is installed in a basic form, but the final version will not be delivered by TRW Inc. until the end of the year because of development delays. In its present form, the system could not, for example, control the telescope so as to track moving targets such as planetary moons. Other systems, such as that which will calculate optimal timing of observations, are still in development. Some upgrading of hardware at STSI is also now thought to be necessary, but their cost, though counted in hundreds of thousands of dollars, is small compared with the software. All agree that it will be easier to complete installation and testing of complicated control systems with the instrument still on the ground.

Giacconi also wants to use the delayed deadline to allow institute astronomers to catch up on their own research and to foster a "more academic atmosphere". Although the official target for institute staff has always been that they would

Weight problems

IMPROVEMENTS to the shuttle recommended by the Rogers commission investigation of the Challenger accident will add weight and could impair the shuttle's ability to put the massive Hubble Space Telescope into a high enough orbit. Although the ideal height would be 360 nautical miles or more, even the unmodified shuttle is unlikely to manage 320 nautical miles.

At this height, atmospheric drag would gradually bring the telescope down: the plan was that a shuttle flight two years or so after launch would boost the telescope up to the desired 360 miles. (Some point out that if NASA by then has an operational orbiter transfer vehicle — at present still on the drawing board — the telescope may even be taken up to 400 nautical miles, where it would be stable indefinitely.) But if the modified shuttle is incapable of getting close to 320 nautical miles, there may be problems caused by orbital decay and atmospheric interference.

NASA officials Fred Wojtalik of Marshall and Frank Carr of Goddard Space Flight Center do not expect there will be problems, however. Keller, at NASA headquarters, points out that the weight of improvements to the shuttle has not yet been determined and thinks the rumoured figure of 12,000 lb may be pessimistic. The more modest weight increases he thinks likely would, he estimates, result in an orbit only 10–15 miles lower than that now planned.

spend 50 per cent of their time on research, in February the figure was still less than 25 per cent. Proposals for guest astronomers will not now be taken until March 1987 to take account of the launch delay.

Last June, the telescope successfully completed its first major test; a thermal vacuum test which used a simulated solar source to investigate heating effects, and other calibrated light sources for basic checks of the major instruments. Although many minor problems were found. none require extensive redesign or rebuilding. The test did, however, indicate that the telescope takes longer than expected to reach thermal equilibrium, necessary to avoid structural distortion. Among solutions being considered are extra insulating material and more solar cells to make more use of heating elements. The thermal vacuum test also included the first end-to-end test of the telescope's science operations and data analysis system.

Commands were successfully sent from STSI via Goddard through a simulated tracking and data relay satellite to the instrument itself. Although STSI sees the test as a major success, it is only a beginning. Just three of the main instruments were tested, and because of the incomplete control system and software incompatibilities with Lockheed, many of the commands had to be translated manually.

STSI has in the past been criticized for failure to control its budget. But Giaccom says that earlier antagonism between the institute and NASA has now disappeared, as "they recognize a competent group when they see one". Independent consultants agree that the institute has performed impressively in a task whose immensity was not fully realized at the outset. One example: software for the telescope is expected to be 1.5 million lines of code. 10 per cent of that thought necessary for the Strategic Defense Initiative.

Much of the work outside the basic control system has been done in-house at STSI, which is managed independently of NASA. STSI is particularly proud of its guidestar selection calalogue, which contains the coordinates of 40 million celestral sources to unprecedented accuracy. Giacconi claims that running a project at a single institute is often more cost-effective than use of external contractors, and criticizes NASA for wanting to contract out development of the telescope's embryonic data archiving system at a cost he estimates at \$20 million. Giacconi claims STSI can develop a basic but operable system for \$0.5 million, and unfavourably compares NASA's decision to the procurement style of the Department of Defense. But he believes STSI has proved itself and speculates that it will be in business in 20 years' time "for son of the Hubble Space Telescope". Tim Beardsley

CORRESPONDENCE:

Sequencing the human genome

SIR—The prospect of sequencing the entire human genome (Nature 322, 11; 1986) raises a number of questions, some answers to which we wish to suggest.

The first is "why?". After all, not only do we not have any idea what we would find in such an alphabetic morass, but we do not even know enough about genomic structure to know what to look for. The fact that such a bizarre project may be "technically feasible" is hardly a justification. It is as technically feasible to excavate the entire country of Kenya to a uniform depth of six metres for hominid fossils, or to determine the wiring diagram of all the synaptic connections in the human brain; but any biologists who proposed such projects would doubtless be obliged to carry them out in a padded laboratory. Similarly, sequencing the genome would be about as useful as translating the complete works of Shakespeare into cuneiform, but not quite as feasible, or as easy to interpret.

A better reason is that such a major endeavour would occupy every living molecular biologist, regardless of competency, for several years, thus solving the growing unemployment crisis. The social consequences of keeping molecular biologists off the streets, where they might develop into thugs, ruffians, land-fraud swindlers, or worse, are obvious. Alternative suggestions, such as obtaining a genetic map of humans using restriction fragment length polymorphisms, suffer in that they would employ clinicians and (far worse) population geneticists and anthropologists. Any sense of social responsibility dictates keeping these latter groups on the streets where they belong. Similarly, all attempts to limit the project to sequencing only a single small chromosome must be resisted, as this would not be sufficiently labour-intensive to employ enough molecular biologists.

Second, whose genome gets sequenced? As both X and Y chromosome sequences are required, women must be excluded from consideration. A haploid set is required as diploids often show an embarrassing amount of variation between homologues. The extraction of such a set will prove difficult, given the scarcity of recorded haploids in human history. As molecular biologists generally ignore any variability within a population, the individual whose haploid genome is chosen will provide the genetic benchmark against which deviants are determined. Much care must be taken in the selection of the exemplary individual to serve as this ultimate genetic role-model: it would be most embarrassing to throw out the first 500,000 kilobases and have to start resequencing a new individual if some character flaw is discovered late in the project.

However, the recent success of obtaining DNA from both an extinct species (Nature 312, 282; 1984) and a mummy (Nature 314, 644; 1985) suggests the possibility of using a venerable deceased human for a subject. This is quite in keeping with the spirit of the proposed sequencing project, as much of its justification involves the creation of new technologies. We would like therefore to be the first to suggest that the genome of the father of modern biology, Charles Darwin, be the one sequenced. We leave it to our English colleagues to arrange to have his remains exhumed from Westminster Abbey for the honour.

Unfortunately, it would hardly honour Darwin's memory, as the conceived sequencing project violates one of the most fundamental principles of modern biology: that species consist of variable populations of organisms. Alas, every dog has his day, and if the molecular vulgarians have theirs, "the" genome of "the" human will be sequenced, gel by acrylamide gel.

And what is to be done, finally, when this sequence is obtained? Perhaps the scientific community can enlist David Wolper to stage a worldwide tribute to the genome, culminating with every person on Earth symbolizing a nucleotide and joining hands to form all 22 autosomes and both sex chromosomes. It would be a fitting finale to a grand scientific project.

Special relativity

SIR—Aspden¹, Psimopoulos and Theocharis2 discuss the need for a Michelson-Morley type test in space and raise interesting points about the effects of standing waves in rotating and translational motion of optical apparatus. Some time ago, I carried out a relevant investigation using a special standing-wave sensor manufactured by the General Electric Co.3. This photoelectric sensor incorporates a photomultiplier tube through which a laser beam can pass to be reflected back on itself by a mirror. This allows the device to scan translationally along the standing wave set up by the interference in the beam. The experiment shows that the spacing between nodes in the standing wave set up by two oppositely-directed light rays from the same laser source is a function of the orientation of the apparatus.

The forced optical condition assuring light speed isotropy as suggested by Aspden is not supported by the experiment, and initial indications are that the beam modulation pattern is attributable to the Earth's motion through space at cosmic speeds commensurate with those found from the isotropy assumption of 3K cosmic background radiation. In effect, it appears that in the standing-wave conditions, the waves move at different speeds in opposite directions relative to the apparatus and, as their frequencies are the same, they present different wavelengths in the two directions and so affect the nodal spacing.

A detailed report on the experiment is available prior to eventual formal publication. Meanwhile, it is of interest to note that the optical configuration resembles that of the Sagnac experiment, the basis of the ring laser gyro technology mentioned by Aspden, Psimopoulos and Theocharis. However, the sensor scans linearly along a section of the modulated beam in a nonrotating system, rather than being at rest, as in the gyro, and sensing effects of rota-

tion of the apparatus.

Clearly, this research will have interesting implications for the theory of relativity, as foreseen by your recent leading article4. It may also help us to resolve the large errors found in the global satellite positioning system. If present findings are sustained, it may not be necessary to extend the Michelson-Morley tests into outer space in order to obtain positive, as opposed to null, results in interferometric tests of linear motion.

Science and faith

SIR-In his review of John Barrow and Frank Tipler's The Anthropic Cosmological Principle (Nature 320, 315; 1986), William H. Press comments that the authors' end "... is nothing less than the fusion of matters of science with matters of individual faith and belief. It has taken us a long time to separate these matters, each to its own legitimate arena in human affairs. We should not lightly allow them to become once again jumbled

Although they are generally accepted, is it helpful to be given such delineations of "legitimate" arenas, which would seem to carry restrictive bias into the unfolding of human thought and experience? I personally find a segmented life no more attractive than a jumbled one.

RICHARD A. McCORKLE

RR1, Box 210, South Salem, New York 10590, USA

What happens on Cygnus X-3?

The notion that a periodic X-ray source may also be giving off streams of massive particles which are unknown from accelerator experiments is still, against the odds, alive.

OUTWARDLY, Cygnus X-3 is a run-of-the mill celestial source of X-rays, first recognized as such (in 1966) by early rocket observations which have since been amply confirmed by measurements from Earth satellites. One of the most striking features of the object is that it is a regularly periodic source of X rays with a period of 4.8 hours, which fits in well with the assumption that it is a binary star, one partner of which is a massive neutron star while the other is a less compact, more "normal", companion.

Cygnus X-3 is also distinguished by its intensity as a source of X rays. Indeed, the source is thought to be rather more than 10,000 parsecs distant from the Solar System, a substantial fraction of the diameter of the Galaxy. But this circumstance goes only to sharpen another puzzling feature of the properties of the object, that it is a source not merely or ordinary X rays but of X rays so energetic that they are properly known as gamma rays. Indeed, there have been suggestions (see, for example, A.M. Hillas, Nature 312, 50; 1984) that a few sources as powerful as Cygnus X-3 might be sufficient to account for the total content of cosmic rays in the Galaxy.

This leads to the most curious and unexpected feature of Cygnus X-3, the sketchy but intriguing suggestion that this very distant binary star may be the source of energetic particles whose nature is at present entirely unknown but which are nevertheless responsible for the production of mu-mesons (muons) at the surface of the Earth. The evidence is sketchy in the sense that it is urgently in need of independent verification, but it is also the kind of evidence that people cannot entirely set to one side.

Observations that suggest some connection between the X-ray star and the detection of cosmic rays at the surface of the Earth go back for several years. In 1983, for example, J. Lloyd-Evans and a group of colleagues at the University of Leeds (see Nature 305, 705; 1983) showed that there is a correlation between the detection of energetic cosmic-ray showers in the atmosphere of the Earth and the phase of the supposed binary source of X rays from Cygnus X-3. Whatever else may emerge about this strange object, two things are clear from the cosmic-ray observations: first, the object is a source of energetic cosmic rays that are detectable at the surface of the Earth; and, second, that the sheer production of energy in the form of energetic particles, say gamma-ray photons, must be very large.

The measurements that have raised new possibilities were undertaken with the equipment installed deep underground in recent years in the hope of detecting the predicted radioactive decay of the proton. An unavoidable complication of these measurements is the background flux of energetic muons, which explains why there have recently accumulated data on the occurrence near the surface of the Earth of muons energetic enough to penetrate at least through the overburden of rock to the subterranean detectors.

The first reports that something remarkable may be afoot appeared just over a year ago (M.L. Marshak et al., Phys. Rev. Lett. 54, 2079; 1985), and were based on measurements of background muons at the proton-decay detector operated jointly by the University of Minnesota and the Argonne National Laboratory. What Marshak and his colleagues claimed is that muons observed deep underground correlate significantly with the phase of the distant X-ray star in its binary orbit. Supporting evidence has been produced by G. Battistoni et al., based on measurements with the proton-decay equipment under Mont Blanc (Phys. Lett. 155B, 465; 1985).

For the past year, the bare bones of the mystery of Cygnus X-3 have been plain for all to see. If there is indeed a correlation between the phase of Cygnus X-3 and the time of detection of energetic cosmic-ray particles of some kind at the surface of the Earth, the implication is that the propagation of some influence over the 10,000 parsecs between the double source and the Solar System must be accomplished in such a way that phase information is not lost on the journey, which in turn implies that differences of travel time over 10,000 parsecs must be a small fraction of the orbital period, a few minutes perhaps.

Since these circumstances were first appreciated, there has been a gale of speculation about the means by which the influence of Cygnus X-3 might be propagated over these distances. First, the precision of the timing implies that the speed of propagation must be a very large proportion of the velocity of light, which in turn implies that if particles are the medium by which the message is transmitted, they cannot be massive-particles. Indeed, Marshak et al. last year gave good reasons why particles as massive as

neutrons would not meet the need, while particles as light as photons were similarly excluded on the grounds that there would have to be more of them than could possibly be consistent with other observations.

K. Ruddick (from the Minnesota group) now takes the argument further by pursuing the suggestion, originally made by Marshak et al., that the intermediary between Cygnus X-3 and the Solar System is a flux of particles that are electrically neutral (so as not to be smeared out by the intragalactic magnetic field), relatively small in mass (so as to preserve the synchroneity of the events) and previously unknown. Ruddick's account of the problem appears in Phys. Rev. Lett. 57, 531; 1986. The essence of his case is that light neutral particles are transmitted from Cygnus X-3 until they meet the rocks of the surface of the Earth, whereupon they are converted into other particles.

In principle, the argument is simple enough. Here is a set of data that cannot easily be explained in terms of existing theories, so why not invent a novel particle to account for what may be happening? The innovation in Ruddick's argument is that the primary novel particles (called "cygnets", which is natural enough given where they come from) do not interact directly with terrestrial nucleons to give the muons observed, but instead do so through the intermediary of a second unknown particle, necessarily more massive than the first. Ruddick argues that neither particle need have been observed in accelerator experiments.

The temptation to mock at the inven ion of a new particle of matter to solve each new problem in astrophysics should be firmly suppressed. By any yardstick, Cygnus X-3 is a remarkable object. Most of what people have written about it has been concerned with explaining how it may function as a source of very energetic X rays. Several models have been ad anced, most of which entail the impact of a particle beam from the neutron star on the more extended envelope of its larger companion. Until the likely spectral distribution of the energy produced by such a process is more exactly known, it will be hard to tell how strong is the case for extra particles. And, meanwhile, there is a great need that the original measurements should be repeated in such a way that people can tell more precisely how critical is the apparent synchroneity of phase. John Maddox

Particle physics

Where now with superstrings?

from Robert Walgate

LITTLE more than a year since superstring theory, the best attempt yet at a 'theory of everything', began to drag particle theorists into its net, superstrings are still "the only game in town" for the unification of forces, including gravity, in a quantum framework. So says Steven Weinberg (University of Texas), who with Abdus Salam and Sheldon Glashow developed the first modern unification of forces, 'electroweak' theory, that combines electromagnetism and the weak interaction. Weinberg gave the summary talk at a recent high-energy physics conference*, where it was clear that superstrings have become an important part of particle physics.

The basic idea underlying superstring theory is that the Universe is a world of many more dimensions than the four now apparent (the number ten is now usually favoured) inhabited by myriad, almost infinitesimal, elastic strings. These strings, sometimes looped, charged, spinning and vibrating, interact to pull the extra (usually six) dimensions into a tiny, closed structure full of gaps and holes that is left attached, almost like hair, to the remaining still-extended four dimensions, a process compactification. Particular arrangements of this stringy hair, such as a string winding once through a particular kind of six-dimensional hole, then lead to the particles we see.

But the theory has its problems. One of them is its uniqueness: the meeting showed that there are at least six candidate theories, all of which seem (so far) to be self-consistent and free of 'anomalies', the hidden quantum violations of charge and energy-momentum conservation that have dogged all other attempts at unification. According to Weinberg, John Schwartz, who with Michael Green launched the first more-or-less realistic anomaly-free string theory, said at the meeting that the number of candidate theories (which differ in the number of dimensions, the exact constitution and charges of the strings) could even increase, although it could decrease again if inconsistences are found in some versions.

Weinberg says the meeting was not perturbed by this development. All the versions of the theory may be the same in substance, each possibly being a different dynamical solution of a single underlying theory. This, according to one controversial view, could take the form of a string theory originally introduced many years ago as a model of the strong interactions: a bosonic string in 26-dimensional space-

*XXIII International Conference on High-Energy Physics, 16–23 July 1986, Berkeley, California.

time. Furthermore, another problem of non-uniqueness in superstring theory, the variety (thousands) of possible fourdimensional worlds it allows, is showing some signs of resolution. "The trouble with superstring theory, though this may not last, is that there don't seem to be any easy problems" says Weinberg. A theory should not be thrown away because it is difficult to use (the equations of hydrodynamics remain true even though it is almost impossible to calculate turbulent flow), but most difficult theories, including hydrodynamics, have certain key simple predictions through which they can be tested. But for superstrings "Schwartz said, and I agree, that there seem to be no decisive tests in sight". So superstrings remain with the theorists.

Weinberg points out that superstring theory has also disappointed early hopes of a natural solution of the 'cosmological constant problem', the question of how gravity behaves as if the vacuum is empty although in all unified field theories it is packed with a hornets' nest of forces and curvatures. Nevertheless the theory has had "many qualitative successes" and remains "a very beautiful theory, partly because of its logical rigidity".

Could there be experimental tests of the existence of strings? The phenomenology of the theories remains "murky", says Weinberg, precisely because of the number of ground-state 'worlds' which are still in practice indistinguishable. There may still be thousands of ground states to explore. One such exploration reported at the meeting requires a "great deal of mathematical virtuosity"; the resulting world' is "very encouraging, in that there are no problems like the proton decay being too fast, and the general pattern of quark and lepton masses looks vaguely reminiscent of the real world". But there are many 'worlds' yet to explore, each requiring its degree of virtuosity, and we may not be able to muster the labour to find the solution.

Although no projected experiments can bear directly on superstrings, there are nevertheless still some experiments of great interest that can be done. Next year should see the first experiments on the Fermilab Tevatron Collider, which will reach 2-TeV collision energies between protons and antiprotons, and the Stanford Linear Collider (SLC), which will be a 'factory' of Z's, the intermediate vector bosons that mediate the neutral part of the weak interaction. The prospect of these experiments, particularly those at the Tevatron, "loomed" over the conference,

says Weinberg. Although they are unlikely to reveal anything directly about superstrings, the SLC experiments should provide "exquisitely detailed" data on the decays of the Z", thus producing fine tests of the 'standard model', (the Weinberg-Salam electroweak theory plus quantum chromodynamics for the inter-quark force). Experiments, especially those with the Tevatron, "are going to settle the question of whether or not there is a vestige of supersymmetry at low energies".

This bears on string theory because superstrings are also supersymmetric, in that for every low-energy particle they create they also create a massive 'superpartner', a partner differing only in its higher mass, spin and quantum statistics. (Thus, if a particle obeys the Pauli exclusion principle, like the electron, its superpartner will not; and if a particle does not obey the exclusion principle, like the photon, its superpartner will do so.) Superpartners are useful in that they help explain why the weak interaction separates from the electromagnetic at energies of just a few hundred GeV, compared with the 1015 GeV or so at which electroweak forces separate from colour (the 'hierarchy problem'). However, superpartners only do the trick if their mass is sufficiently low. The Tevatron should see squarks, the superpartners of quarks, if their masses are less than 200-300 GeV, "a very plausible mass for them to have". If the Tevatron sees no superparticles, supersymmetry will lose its value in the hierarchy problem, and hence half its motivation. If the superpartners are found, on the other hand, we will know the masses and interactions of these long-dreamed-of particles, and "I can't even imagine what impact that's going to have on our models" says Weinberg. Superstring theory, however, could survive a non-discovery: the Calabi-Yau compactifications of the six extra dimensions were chosen, in part, to produce low-energy supersymmetry. It should be possible to find other classes of solution to the superstring equations that push the superpartner masses higher.

On other experimental issues, Weinberg is convinced by contributions at the meeting that there is a scientific "no-lose theorem" for results from the proposed superconducting supercollider (SSC), a 20-TeV collider now awaiting a decision on its construction from the US Department of Energy. Rigorous calculations in which space-time is approximated as a lattice (a common technique in modern quantum field theory) show that the SSC must reveal the origin of the symmetry breaking that divides electromagnetism from the weak interaction at low energies. This mechanism could either involve a vacuum full of a 'Higgs field', or a new superstrong 'technicolour' force that could lead to strong interactions between intermediate vector bosons. According to

this no-lose theorem, the Weinberg-Salam electroweak theory, which is a lowenergy approximation invoking the Higgs mechanism, must break down to some 'new physics' at an energy that depends on the mass of the lightest observable Higgs particle. If the Higgs mass is low (100 GeV), the breakdown does not appear until 1019 GeV where quantum gravity enters and new physics is certain. If the Higgs mass is only 10 times higher, new physics sets in "almost immediately". In either case, the corollorary for the SSC is that there will be something fundamental to observe: either Higgs at 100 GeV; or both Higgs and the new physics, possibly technicolour.

Solar neutrinos were also central to discussions at the meeting. The new 'resonance' mechanism explains the low incidence of solar neutrinos in Raymond Davis's electron neutrino detector at Homestake Mine, South Dakota in terms of a resonant, efficient conversion of solar electron neutrinos into higher-mass neutrino species in the Sun. This mechanism requires the neutrinos to have masses that turn out to be of exactly the order predicted by a wide class of unified field theories, according to Weinberg, who presented very general arguments that the mass of the heaviest neutrino should be around the square of the top quark mass divided by the grand unification scale (about 1015 GeV). This works out at around 10⁻³ eV. whereas the solar resonance model is tolerant of a range from 10⁻³ to 10⁻⁵ eV, depending on mixing angles between neutrino types. Weinberg argues, therefore, that a test of the resonance model is now "as important as anything else in particle physics". Several experiments are already at proposal stage. The best method would be to look for weak neutral current interactions of the solar neutrinos arriving at the Earth, Weinberg suggests, because all the incoming neutrinos would interact equally, the neutral current being 'democratic' in neutrino types.

If the Davis experiments, which measure charged-current interactions, are seeing few electron neutrinos because there are fewer of these particles produced in the solar core (perhaps because the temperature is lower than expected) then a neutral current experiment will see the same number. But if the threefold depression below predicted rates that Davis sees is caused by the conversion of two-thirds of the electron neutrinos to other neutrino types, then a neutral current experiment will see three times Davis's signal. Weinberg says that this experiment "may be our lucky break", the only indication of the grand unification of forces that comes down to us from 10¹⁵ GeV, now proton lifetimes seem too long to detect.

Planetology

Sulphur and volcanism on Io

from David A. Crown and Ronald Greeley

SULPHUR on Io was suggested even before Voyager 1 and 2 flew by the jovian system in 1979^{1,2}, and although its existence is now generally accepted, its precise role remains controversial. The morphology of volcanic landforms argues for a surface formed by silicate volcanism, whereas spectral data indicate a surface dominated by sulphur (see ref. 3 for review). Lunine and Stevenson' recently presented a model for hot spots, regions of intense volcanism on the surface of Io, as lakes of molten sulphur.

Active volcanoes were observed on Io

into account the physics of convecting, boiling systems and the transport of vapour away from such systems. The authors suggest that the temperatures and thermal fluxes observed in the Loki Patera region of Io (see figure) are consistent with their model of a convecting sulphur lake and that the total thermal flux is consistent with the maximum that could be derived from a convecting silicate magma chamber. Their model also explains the distribution of thermal energy around Loki Patera observed during the Voyager missions and indicates that evaporation

constrains the maximum surface temperature of a sulphur lake under steady-state conditions.

Lunine and Stevenson's model provides the means to relate the surface heat detected by Earthbased infrared observations to changes in the temperature of a sulphur lake and variations in the output of silicate magma chambers in Io's crust. The authors estimate that if lake renewal or magma chamber lifetimes are limited to years, then changes in the thermal output in detected based observations at

Voyager I mosaic showing the eruption of Loki (lower left). Plumes emerge from a linear black fissure approximately 200 km long. The crescent-shaped large dark patch to the left of the fissure may be a lava lake with a section of solidified crust in its interior. Other vents are seen in the image as dark, nearly circular patches surrounded by lava flows and volcanic plains. The original mosaic was processed by A.S. McEwen (Arizona State University) and the US Geological Survey.

during the Voyager I and 2 missions and are attributed to the dissipation of tidal energy resulting from the configuration of Io's orbit in the jovian system'. McEwen et al.', using Voyager infrared interferometric spectrometer results and multispectral data, correlated dark calderas with areas of high heat flow. Recent experiments concerning the optical properties of sulphur are consistent with this correlation and indicate that molten sulphur on the surface of Io would be black as observed by Voyager instruments'.

Lunine and Stevenson explain the hot spots using a model for a convecting sulphur lake heated by an underlying silicate magma chamber. The model considers the physical and chemical processes in convective sulphur lakes, including the thermodynamic and transport properties of sulphur and the effects of some possible impurities. In addition, the model takes

infrared wavelengths are important to distinguish between: (1) high temperature (600 K) outbursts isolated from the Loki region (volcanic eruptions); (2) independent changes in warm or hot components in the Loki region (the warm component, the result of the latent heat released on condensation of evaporative sulphur in the atmosphere surrounding a sulphur lake, and the hot component caused by the heat released by convecting molten sulphur); and (3) changes in sulphur lake temperature and the corresponding evaporative sulphur flux. Consequently, Earth-based monitoring could provide important information about Io's thermal output and volcanic activity.

Lunine and Stevenson also consider the effects of impurities such as sodium polysulphides. If the base of a sulphur lake became enriched in sodium polysulphides, convection of this material might

occur and a liquid polysulphide melt could be exposed at the surface on evaporation of the overlying sulphur. Sodium polysulphide lakes or remnants of such lakes may occur in the Loki Patera region and elsewhere on Io and could be distinguished from convecting sulphur lakes using infrared observations at several wavelengths. Lunine and Stevenson suggest that such polysulphide lakes could be the source for the sodium-enriched material in the Io torus.

Although many assumptions are involved, Lunine and Stevenson's rigorous application of theory to both Earth-based and Voyager observations demonstrates the importance of continued monitoring of Io from Earth and is an example of the type and quality of work necessary to plan future observations effectively. In particular, the sulphur lake model can be

evaluated during the Galileo mission in I the 1990s. Lunine and Stevenson suggest that during the cruise phase of each orbit. thermal measurements, including those from the night side of Io, could be used to characterize and to detect variations in hot-spot activity.

Plant viruses

New threats to crops from changing farming practices

from Robert Coutts

In the 25 years since it was first suggested that root-inhabiting fungi act as vectors of plant viruses', many such viruses have been identified and some characterized in detail (see ref. 2 for a recent review). The importance of these viruses as plant pathogens in the United Kingdom was largely ignored until recent changes in agricultural practice as well as the geographical proximity of the fungus-vectored viral agent of rhizomania, beet necrotic yellow-vein virus, renewed interest'. Will an increased awareness of the incidence of soil-borne viruses or further changes in agricultural practice result in the appearance of further 'new' viruses and their associated diseases?

Of immediate concern to farmers in the United Kingdom is the spread of barley yellow mosaic virus^{4,5} carried by zoospores of the primitive plasmodiophoromycyte Polymyxa graminis Ledingham, that affects winter barley. (Beet necrotic

Infected barley root cell full of resting spores (cystospori) of P. graminis, the vector of barley yellow mosaic virus. (Photograph courtesy of E.J.F. Roberts and K.G. Laing.)

yellow-vein virus is transmitted by another member of this group, P. betae Keskin.) The barley virus is widespread, causing variable reductions in grain yield, because farmers now grow winter malting barley as a profitable spring crop. Local soil conditions, such as low temperature and high humidity, are ideal for fungus transmission of the virus and the development of symptoms. As temperatures rise in the spring the symptoms of the disease fade but infected plants remain stunted.

After transmitting the virus to the plants, the zoospores develop into cystosori which are found in the roots and which can remain viable for extended periods (see figure). This feature of the fungal life-cycle ensures perpetuation of the fungus and virus in areas of intensive winter barley production. Recent reports of the incidence of more than one naturally occurring strain of the virus' suggests any inbred resistance may not be durable.

In the long term, biological control of Polymyxa with other rhizosphere-inhabiting microorganisms may be possible. For example, cystosori of P. betae can be parasitized and completely degraded by Trichoderma harzianum Rifai in vitro¹, offering hope for the control of rhizomania, the sugar-beet disease that causes havoc in Europe. This disease and the causal agent, beet necrotic yellow-vein virus, have recently been diagnosed in France, the Netherlands, Belgium and Luxembourg. Import of sugar-beet stecklings from Europe to the United Kingdom is now banned³.

P. graminis and P. betae can be differ-

entiated only by host specificity, and the spread and transmission of the beet and barley viruses described here appears similar. A recent survey8 failed to find the beet virus or the disease in the United Kingdom but does reveal the presence of a morphologically similar but serologically distinct virus8. This virus, or one very similar to it, had been isolated previously from beet plants in Norfolk displaying root-symptoms of the Barney patch disorder. The virus, provisionally named beet soil-borne virus, is also apparently transmitted by P. betae but its pathogenic effects, if any, are unknown. The catastrophic effects of rhizomania are well documented, with the sugar content of infected beets reduced to 10 per cent or less of that found in uninfected controls³.

Changes in horticultural practice have increased the incidence of another group of fungus-borne viruses whose appearance coincides with the increased growing of plants in soil-free environments, where plants are cultivated on solid-support matrices and fed with liquid nutrients. Nutrient-film growing is popular with growers for several reasons, such as its application to greenhouse crops, ease of maintenance, monitoring of nutrient supply, quality control and cost. But two outbreaks of disease in the last six years, lettuce big vein virus and necrotic spot virus in cucumber seem to be a direct result of nutrient-film growing.

The lettuce and cucumber viruses are transmitted by zoospores of the aquatic phycomycetes Olpidium brassicae and O. radicale, respectively. However dissimilar from the situation with the plasmodiophoraceous fungi, chemical control of phycomycete fungi and the diseases they transmit appears feasible — the two outbreaks of lettuce and cucumber viruses were successfully controlled by continuous application of a non-ionic liquid surfactant that killed the transmitting zoospores 9,10

It is unlikely that the viruses I have described in this article are new to the United Kingdom. It is more plausible that interactions between the viruses, vectors and hosts are now acting under the correct environmental conditions for infection to result.

Atmospheric chemistry

Hunting tropospheric OH ions

from D. Perner

Is the self-cleansing capacity of the troposphere still adequate to cope with the ever-increasing amounts of emitted gases? Or could unchecked anthropogenic emissions eventually make populated areas uninhabitable? To measure accurately concentrations of the free hydroxyl radical (OH), generally regarded as the main agent for direct oxidation and for removal of substances from the atmosphere, has been a major challenge14. The article by Hard and co-workers on page 617 of this issue' describes measurements obtained by a promising new spectroscopic technique which should allow a test of whether

Comparison of the diurnal variation of measured OH concentrations × 106 ml⁻¹ (left-hand scale) observed by optical absorption on 19 May 1983 at Deuselbach (black circles), and by laser-induced fluorescence⁵ on 18 June 1985 at Portland (crosses). Also shown are the O_3 photolysis frequency \times 10^{-5} s⁻¹ (right-hand scale; dotted line) and the calculated OH concentration (open circles), both for Deuselbach*.

our understanding of atmospheric photochemistry is consistent with measured OH concentrations.

It is only since the early 1970s that the central role of the OH free radical in the troposphere has become apparent. In 1969 Weinstock⁶ ascribed the strong variability of carbon monoxide in the troposphere to the action of OH radicals, but he could not identify their source. Two years later, Levy found that not all of the Sun's ultraviolet light, which produces excited oxygen atoms from ambient ozone, was filtered out by the stratosphere. Because this excited oxygen is the primary intermediate for OH formation, an appreciable source of OH therefore exists in the troposphere.

Although highly labile, OH does not react with any of the major atmospheric components, so it can exert its full oxidative power on trace gases such as methane, carbon monoxide and methyl chloride, which are eventually converted into carbon dioxide, water and other

stable products that are washed out of the atmosphere. This process has prevented trace compounds from building up in the atmosphere over the millenia. OH is important because it is regenerated in these oxidation processes: in the free atmosphere, typically up to five oxidation reactions are initiated by OH before it is scavenged. Despite this amplification of OH, fast chemical reactions keep its ambient concentration quite low, to about a few million molecules per millimetre in sunlit air. It is also commonly accepted that the concentrations at night are considerably below those in the daytime.

Several in situ techniques for measuring OH concentrations are presently in use. Radiolabelled products, such as ¹⁴CO, formed from ¹⁴CO by the OH reaction, can be measured with high-sensitivity or spectroscopic methods to probe the OH concentrations directly¹⁻³. Hard et al.⁵ apply laser-induced fluorescence at low pressure in a manner that excludes ambient light from the detector. In this way difficulties previously found using this technique are circumvented and the instrument can be converted easily for aircraft measure-

The midday OH concentrations found in Portland by Hard et al.5 can be compared with similar observations in Deuselbach by my own group obtained by longpath optical absorption (see figure). Whereas in Deuselbach the OH signal disappears at 1700 h, the OH in Portland

extends fairly late into the evening and, surprisingly, is found at night. The reason for this unexpected and interesting observation is unknown. Other types of data from Portland are not detailed enough to calculate a model of the OH distribution. In contrast, other types of data from Deuselbach predict much higher OH concentrations than are found experimentally there. Thus the theoretical description at Deuselbach cannot be applied.

I still believe that direct evidence for free tropospheric OH, preferably by spectroscopy, is needed. Simultaneous measurements of all species and parameters in the OH photochemical cycle. together with the OH measurements, are now a prerequisite to test our atmospheric theory. Investigations of various air masses should be made to represent the whole of the troposphere, and then we could distinguish between the importance of homogeneous gas-phase chemistry and heterogeneous processes taking place at the surface of aerosols or in droplets. Only then shall we learn whether the observed increase in concentration of climate-effective gases like methane is caused in part by a decline in atmospheric self-cleansing by OH.

Archaeology

Japanese agricultural beginnings

from Gina L. Barnes

AGRICULTURE in the Japanese islands was long thought to begin with the importation of wet rice technology from the continent at around 300 BC, an event taken to mark the transition from a hunting and gathering economy in the postglacial Jomon period to a period of settled agricultural communities. But this traditional view has been thoroughly overturned in the past ten years with discovery of the remains of many cultivated plants — including rice from Jomon sites'. The recovery of buckwheat pollen from the Ubuka bog in southwestern Japan, reported on page 632 of this issue2, provides the strikingly early date of 6,600±75 years before present (BP) for buckwheat cultivation, paralleled only by the finds of beans and gourd at the Torihama site which are dated to 5,000-

3,500 BC. If these data become widely accepted, they may lead to a substantial revision of our ideas about the pattern of human settlement during this period

Models allowing flexibility in determining the role of plants in the different regional and temporal complexes of the Jomon period have already been developed^{3,4} and a major advance has been the correlation of population densities with forest and fishery zones'. This correlation indicates that the population occupying the southwestern evergreen oak-laurel forest at low density was less dependent on hunted animals - scarce in such a forest regime - and therefore more dependent on plant foods. The abundant floral remains at Torihama from the early Jomon period support this idea and

Akazawa believes this background accounts for the rapid spread of rice agriculture through western Japan once it was introduced from the continent towards the end of the Jomon period⁷. His corollary is that the populations of coastal northeastern Japan that had highly successful fishing economies resisted the introduction of rice technology.

The beginnings of plant cultivation in western Japan are based on the concept of the 'Laurilignosa culture' developed by Nakao (see ref. 8). The composition of the evergreen oak-laurel (Laurilignosa) forest that became established around 7,000 BC was part of a greater continental forest zone occupied by people practising 'slash and burn' agriculture. The extension of this economy into the Japanese portion of this forest zone is held by numerous Jomon archaeologists who have interpreted charred layers in excavation stratigraphy as the remains of burnedforest fields. Although slash and burn systems that include systematic fallowing cannot yet be distinguished stratigraphically from simple forest-clearing activities using fire, Tsukadas not only shows the sudden appearance of charcoal fragments in the Ubuka bog cores but he also provides palynological evidence for the crops being grown — in this case buckwheat.

Most evidence for Jomon cultivation has been in the form of macroremains or seeds (for example, see ref. 9). Methods of identifying cultivated plants from fossil pollen and plant phytoliths" have only recently been refined to the point of credibility, and palynological evidence is still viewed with scepticism by many Jomon archaeologists. Tsukada's method of filtering out large pollen grains in order to count the percentage occurrence of buckwheat is still unpublished, and his identifications of millet pollen remain tentative". Moreover, the method used by Japanese palynologists to identify rice pollen (see ref. 12) is not yet complete.

Nakamura's method combines transmission electron microscopy and phasecontrast microscopy, by which three groups of grass pollen are distinguished according to their surface morphologies. Nakamura states that this is at best a method for tentative identification, for although rice (Oryza) can be distinguished from pollen of the other types, it cannot be

distinguished from Agropyron (Graminae) and Arundinaria (Bambusoidae); both of which grow in similar ecological niches as Oryza.

Nevertheless, Nakamura and colleagues have identified rice pollen in Jomon sites dating to 1,200, 1,000 and 900 BC (for example, ref. 11). Japanese archaeologists are reluctant to accept these early dates, however, and still consider the appearance of rice-growing in Japan at around 400 BC on the basis of archaeological evidencé of field systems and rice

Clearly, research on the different crops and their cultivation systems in the Jomon period of Japan is extremely controver-

sial, with various disciplines offering differing forms of evidence and interpretations. The debates may lead to substantial revision of ideas on the Jomon, once thought to be a very stable and long period of foraging, and may reveal a number of adaptive strategies and mixed subsistence economies existing through time and space". These results are important not only for Japanese prehistory but also for understanding changing human-plant relationships throughout the world in the postglacial period.

Invertebrate neurobiology

Catching up with peptides

from Mark Tyrer

Our knowledge of the structure of most bioactive peptides in invertebrates is too scanty to exploit the experimental advantages provided by their large, accessible central neurones. If we could use these advantages to the full, invertebrate neurones could provide model systems for testing at the cellular level some intriguing hypotheses about peptide function in the vertebrate central nervous system. Paradoxically, the small size of the invertebrate nervous system, which makes it so attractive for physiology, is an obstacle to isolating and sequencing native peptides. At a recent meeting* it was clear that many invertebrate peptides are now beginning to yield to developments in high-pressure liquid chromatography, amino-acid sequencing and recombinant DNA technology. These developments mean that the small amounts of nervous tissue available from invertebrates are becoming less of a problem and the distribution and function of some native peptides are now being studied in detail.

The structures of several invertebrate peptides have now been deduced, including the crustacean cardioactive peptide CCAP, a nonapeptide different from any previously described peptide in that it has two cysteine residues which are thought to form a disulphide bridge, producing a hairpin shape (J. Stangier, Bonn). A neuropeptide from the sea anemone Anthopleura and three new peptides from Aplysia have also been sequenced. Insect diuretic hormone has been partially sequenced and others, such as argininevasopressin-like insect diuretic hormone (AVP-DH); a moth pheromone-releasestimulating peptide; and a crustacean moult-inhibiting hormone, are on the way.

Invertebrate Peptides and Amines, Bordeaux, 16-18 April 1986, to be published in the seminar series of the Society for Experimental Biology.

The purification of prohormones for invertebrate peptides is particularly exciting. Because several peptides are com- ... monly cleaved from one prohormone, cleavage products may include, in addition to known peptides, some which have not yet been identified. The prohormones for locust AVP-DH, locust adipokinetic hormone, Aplysia pro-FMRF amide (Phe-Met-Arg-Phe-NH,, or Femerfamide) and snail ovulation hormone have been isolated. The amino-acid sequence of the FMRF-amide precursor (R. Scheller, Stanford University) has been obtained by recombinant DNA techniques. It contains multiple copies of FMRF amide, a single copy of Phe-Leu-Arg-Phe-NH, (FLRF amide) and three regions that have some amino acids in common with mammalian corticotrophin, melatonin-stimulating hormone and corticotrophin-like internal peptide.

Several peptides produce membrane changes in target cells in preparations such as the motor nerve net of the coelenterate Polyorchis (A.N. Spencer, Edmonton), and central neurones in Aplysia (Scheller) and Helix (G. Cottrell and N.W. Davis, St Andrews). In leg muscle cells in locusts and cockroaches, M. O'Shea (Geneva) demonstrated the value of invertebrate preparations for examining the interactions of peptides with other transmitters. All the neurones innervating the muscle have been identified and are accessible to intracellular recording and biochemical analysis. The classical transmitter L-glutamate and the peptide proctolin co-exist in the slow motor neurone to the coxal depressor muscle. Proctolin released from this neurone amplifies the twitch responses of the muscle to coreleased glutamate. At the same time proctolin causes a direct slow contraction of the coxal depressor muscle that seems

to result from release of intracellular calcium. Octopamine released from another motor neurone also amplifies glutamate-induced contractions in the extensor tibialis of the insect. It is probable that cyclic AMP is the second messenger for octopamine and that inositol phosphates mediate the action of proctolin.

Because it has been so difficult to purify invertebrate bioactive peptides many researchers have used antibodies directed against vertebrate peptides for immunohistochemistry on invertebrate systems. Immunoreactivity to vertebrate neuropeptides can provide useful anatomical information; it can also be used to purify a native peptide, either as an effective assay (H. Duve and A. Thorpe, Queen Mary College, London; J. Proux et al., Bordeaux) or as a useful ligand for immunoaffinity chromotagraphy (Proux et al.).

The importance of peptides for signalling in nervous systems is becoming increasingly apparent. Most neurones, both in invertebrates and vertebrates, probably contain peptides as well as classical neurotransmitters. Whereas classical transmitters are released at specialized synaptic junctions, exocytosis of granule-containing peptides often occurs at unspecialized regions of the plasmalemma. This was first recognized in the central nervous system of the earthworm (D. Golding, Newcastle) and is now widely seen if tannic acid (which appears to prevent immediate dispersion of the exocytosed granule) is used in fixing specimens for electron microscopy. Both Golding and J. Joosse (Amsterdam) suggested that peptide transmission is the more primitive method of signalling; classical synaptic transmission could be a specialized development to produce a highly efficient but more inflexible means of information transfer. Joosse argued further that peptides, because of their close relationship to the genome, can be viably altered by any change in the DNA and hence can easily alter their function. Thus, although they may be a less precise method of signalling than classical transmitters, peptides could be involved in adaptation of individuals or populations to changes in the environment.

Gene regulation

Fingers and DNA half-turns

from Stephen C. Harrison

AT first sight the DNA sequences from eukaryotic transcriptional control regions give an impression of overwhelming complexity. The precedent of prokaryotic control suggested simplification should come from structural analysis of the proteins that recognize these sequences; and indeed it seems that understanding of transcriptional regulation of 5S RNA genes in the toad Xenopus laevis has now reached this stage'. At least three protein factors are required for transcription of these genes by RNA polymerase III. One of them, transcription factor IIIA (TFIIIA), has in its amino-acid sequence an approximately 30-residue motif repeated nine times, probably corresponding to nine zinc-binding sites². In the 4 July issue of Cell, Rhodes and Klug³ point out a corresponding repeat in the sequence of DNA bound by TFIIIA and suggest that it has some unusual structural features. Moreover, they identify similar repeats of approximately 5 base pairs (bp) in control regions of other genes, including some transcribed by RNA polymerase II. The possibility that these DNA sequences have overall structural features important for recognition by transcription factors is also raised directly by the report of McCall et al. on page 661 of this issue⁴. They describe the crystal structure of a double-stranded nonadeoxynucleotide that corresponds to the tightest binding

part of the sequence recognized by TFIIIA and show that it has an A-type rather than a B-type conformation.

There are two multigene families for 5S RNA in Xenopus, differentially expressed in oocytes and in somatic cells, respectively'. A single molecule of TFIIIA binds to an approximately 50-bp control region in the middle of the genes, and this interaction is essential for the formation of a transcription complex that directs accurate initiation by RNA polymerase III^{5,6} The site has been defined by deletion mapping⁷, by DNase I protection and by binding interference from base methylation or phosphate ethylation8. TFIIIA also forms a 7S complex with the 5S transcript, and immature oocytes store a vast number of 5S RNA molecules in the form of this 1:1 complex⁹. Proteolytic cleavage of 7S particles divides the TFIIIA polypeptide, which has a relative molecular mass of 40,000 (40K), into two domains — a 30K amino-terminal domain with full binding activity and a 10K carboxy-terminal domain essential for transcriptional activation¹⁰. One amino-terminal domain binds to 50 bp of DNA, and Smith et al. 10 postulated a very extended structure for the protein. Miller et al.2 show that the complementary DNA-derived amino-acid sequence of the 30K domain has nine units of an approximately 30-residue, tandemly repeated motif. Each copy of the motif

contains two cysteine and two histidine residues in conserved positions. The 7S TFIIIA/5S RNA complex contains Zn, and TFIIIA requires this ion tor DNA binding. In proteins, Zn is generally tetrahedrally coordinated, often by cysteine or histidine side chains, and indeed Miller et al. find sufficent Zn in the 7S particles to propose that each 30-residue motil constitutes a Zn-binding 'finger'. The 30K, DNA-binding domain of TFIIIA thus appears to be a nine-finger repeated structure.

Sequence comparisons indicate the presence of similar motifs in other proteins that interact with DNA or RNA. These include the small RNA-binding protein encoded in the gag genes of retroviruses; the E1A gene-activating protein of adenoviruses; and the large-T antigens of papovaviruses. An even more extensive similarity has been found between TFIIIA and the product of the Drosophila developmental, regulatory Krüppel locus. Thus TFIIIA probably represents a class of structures, with a metal-binding site as a significant element of organization.

If TFIIIA contains a nine-finger repeat. is there a corresponding repeat in the 50bp intragenic control region to which it binds? Rhodes and Klug present evidence for such a repeat in the DNA itself. not obvious from casual inspection, but revealed by quantitative study of DNase I cleavage patterns and by mathematical analysis of the sequence. Cleavage of defined restriction fragments at different positions by DNase I is strikingly nonuniform, suggesting strong dependence of the cleavage rate on details of local DNA backbone conformation. DNase I binds across the minor groove, cutting each strand separately¹⁴. Activity may be influenced by the width of the minor groove or the orientation of phosphates A periodicity in the probability of DNase I cleavage along a given strand therefore probably reflects a periodicity in the DNA

Rhodes and Klug's Fourier analysis of DNase I cleavage patterns of the TFIIIA binding sequence shows a periodicity of about 5.7 nucleotides. The periodicity is characteristic of both strands, with a relative stagger of about 1, rather than 2 or 3 as generally observed for B-type DNA The smaller stagger suggests that base pairs are tilted, as in A-form DNA, so that phosphodiester bonds staggered by only one step lie nearly under each other across the minor groove14. Recognition of an Aform structure would of course be convenient for a protein that must bind specifically to RNA as well. Rhodes and Klug³ also observe an approximately 5.6base perodicity in the sequence of the TFIIIA binding site by focusing on the distribution of guanines. Fourier analysis confirms the significance of this repeat, which is not characteristic of randomly

selected nucleosome core DNA. The total of nine such repeats in the internal control region of the 5S RNA corresponds precisely to the nine putative binding fingers in TFIIIA, each of which would tend to make the same sort of contact with DNA.

The crystal structure of a 9-bp doublestranded deoxyribonucleotide with the sequence d(GGATGGGAG) representing base pairs 81-89 of the TFIIIA binding site, is reported in this issue. It supports the notion that the 11-bp repeat $(2 \times 5.7 \text{ in})$ the DNase I analysis or 2×5.6 in the sequence periodicity) and the 1-bp DNase I cleavage stagger observed by Rhodes and Klug3 do reflect an A-type conformation. The structure has been determined and refined at 3.0 Å resolution. It has a mean twist of 31.3°, corresponding to a loosely defined helical repeat of 11.5 bp, and an overall configuration rather close to the model derived from fibrediffraction studies of A' RNA15. The major groove in A-DNA is narrower and deeper than in B-DNA, but the structure determined by McCall et al.4 shows that there is room for a loop of polypeptide to fit — for example, the twisted β -ribbon suggested as a model for a single TFIIIA finger. McCall et al. propose that the GpG steps are the origin of the A-form structure for this fragment. In all structures with GpG/CpC observed to date, the five-membered ring of one guanine base lies stacked on the six-membered ring of its neighbour, an apparently favourable base-to-base overlap that is characteristic of A-form double helices.

The significant conformational plasticity of DNA gives rise to a caveat, however, which McCall et al. discuss. The A structure often occurs in crystals of oligonucleotides — perhaps more often than for the corresponding sequences in solution — and the relationship between solution and crystal conformations is not completely understood. In particular there are unknown influences of endeffects; of electrostatic interaction; and of solvent dielectric constant (the crystals studied by McCall et al. were prepared in 20 per cent methylpentanediol). Nonetheless, it is probably safe to assume that a structure found in a highly hydrated crystal will not differ drastically in free energy from whatever configuration dominates in solution and that the crystal structure represents an important component of any equilibrium distribution.

The significance of the half-turn repeat discovered in the internal control region of 5S RNA genes is enhanced by indication of similar repeats in other control elements. Rhodes and Klug' present evidence for a repeated motif of pairs of guanines within the split transfer-RNA gene promoter of various eukaryotes and within homologous positions of Alu sequences. They also observed that the so-called 21-bp repeats in Simian virus 40

(ref. 16), three tandem elements known to bind transcription factor Sp1 (ref. 17), have an effective 5 1/4-bp periodicity that is particularly striking when the positions of guanines are analysed. They propose that many factors directing transcription of transfer RNA genes by RNA polymerase III, as well as Sp1, which directs transcription by RNA polymerase II, contain TFIIIA-like fingers that interact with halfturn sequences of DNA.

The modular character of this proposed one-finger/one-half-turn correspondence is its most striking feature. Because there is good evidence that TFIIIA binds to one side of the DNA helix18, it is plausible that the fingers project alternately into the major groove on either side of the double helix. Evolutionary schemes can be constructed that would add modules and modify local binding affinities if such a linear relationship between protein modules and DNA half-turns indeed turns out to be true. The position of introns in the TFIIIA, most of which lie just between the putative fingers, is certainly consistent with these ideas19

Such an evolutionary history does not, however, imply that the repeat structures in TFIIIA bind independently. Indeed, analysis of binding to deletion mutants in the TFIIIA site, preferential proteolytic cleavage patterns and fragment-binding experiments all suggest that the aminoterminal part of TFIIIA, the 20K segment that corresponds to the first five repeats, binds as a unit^{7,10}. Moreover its binding is required for binding the next part of the protein (the remaining four repeats). The nine fingers might be grouped into two hands.

Several bacterial control proteins have a different but equally striking modular character. The recurring module is a 20residue helix-turn-helix elbow first identified in the cro repressor protein of bacteriophage lambda²¹ and in the catabolite activator protein of Escherichia coli²². This structure has so far always been found embedded in a larger DNA-binding domain (60-90) residues) of a dimeric or tetrameric protein. The 2-fold symmetry of the protein corresponds to an approximate 2-fold symmetry in the DNA sequence with which it interacts. Contacts to the DNA backbone, made by residues at various positions in the binding domain, position the helix-turn-helix module to interact with bases in the major groove. In most cases, the points of major-groove interaction by the two members of the dimer are one turn apart, although in at least one case, the interaction may be two turns apart²⁴. The repressor of bacteriophage 434, for which the crystal structure of a complex with operator is known. exhibits a specificity for B-form DNA23. The same seems to be true for other helixturn-helix-containing proteins. This sort of modularity found in the prokaryotic repressors and activators is different from that proposed for TFIIIA, most simply because it involves a nearly precise 2-fold symmetry rather than approximate translational symmetry, and structurally because it involves identical protein subunits associated as dimers rather than homologous units concatenated in a single polypeptide chain.

TFIIIA and many of the prokaryotic repressors and activators have one significant structural characteristic in common. One domain directs DNA binding, while a second mediates formation of functional complexes with other proteins. For example, cooperative binding of the lambda repressor at adjacent operator sites is brought about by interacting carboxyterminal domains25, and this interaction is also a model for loop-forming contacts between proteins bound at more distant sites26,27. The carboxy-terminal domain of TFIIIA is essential for correct transcriptional initiation, presumably because it binds to other components of the transcription complex.

There are hints of further structural classes for DNA-binding domains of sequence-specific transcription factors. The yeast GAL4 protein, which binds to upstream activating sequences, and the Simian virus 40 large-T antigen, which regulates transcription and stimulates DNA replication, may contain elements that are examples of such classes. The lesson of progress with TFIIIA is that structural characterization of such proteins and careful analysis of their binding sites can indeed make the apparent complexity of control sequences much less bewildering.

SCIENTIFIC CORRESPONDENCE-

The stability of biological nomenclature: veasts

SIR—The strictures of Erzinclioglu and Unwin on the inconvenient instability of zoological nomenclature (Nature 320, 687; 1986) apply equally to other kinds of organism, including the yeasts. For nontaxonomists, the rapidity with which yeast names change is farcical. For example, Zygosaccharomyces fermentati' was altered to Saccharomyces cerevisiae by Lodder and Kreger-van Rij in 1952, back to Zygosaccharomyces fermentati by Kudriavzev in 1954', to Saccharomyces montanus by Phaff, Miller and Shifrine in 19564, to Torulaspora manchurica in 1975 by van der Walt and Johannsens and finally (?) back again to Zvgosaccharomyces fermentati by von Arx and his colleagues in 1977. The same process continues even now. As part of a major work on yeast taxonomy, C.P. Kurtzman gave descriptions of thirty species of the genus Hansenula, which he then proceeded to abolish in a paper published the same years.

Part of the trouble comes from the romantic confusion of biological classification with evolutionary studies, exemplified by S. J. Gould's words":

"taxonomies are not neutral hat-racks for the pristine facts of nature. They are theories that create and reflect the deep structure of science and human culture.'

Too many taxonomists appear to subscribe to this kind of sentimental codswallop and seem quite unable to understand that instability of nomenclature seriously impairs the value of their work to biology as a whole. How many biologists who work with yeasts know that publications on Saccharomyces carlsbergensis, Saccharomyces uvarum, Saccharomyces cerevisiae or Saccharomyces logos might refer to the same yeast? At best, this is an inconvenience; at worst, it retards understanding of the biology of that yeast.

It would be perfectly practicable for there to be an international body, responsible for the nomenclature of each group of organisms, and briefed to give their names helpful stability.

Microtubule assembly in the axon

SIR-Bamburg et al. (Nature 321, 788; 1986) present a novel view of microtubule assembly in the axon. They show that axonal elongation can be inhibited by an application of microtubule depolymerizing drugs or taxol at the growth cone. The same concentrations of these drugs applied to the neurite or cell body have no effect on motility. The authors conclude that the drugs may act by inhibiting microtubule assembly at the distal tip of the axon. They also postulate that unassembled tubulin is transported along the axon to the growth cone, and there adds on to existing microtubules.

presented, the experimental measurements of axonal length with time are interpreted as a reflection of the extent of microtubule assembly. Such measurements of extent cannot be used to distinguish between effects of the drugs on the rate constants for assembly or disassembly. The microtubule-depolymerizing drugs could act by increasing the rate of disassembly at the tip. For this alternative explanation to hold, one must postulate only that microtubules at the growth cone, but not along the neurite, are in dynamic equilibrium with a pool of monomer. There is no need to require that a net assembly reaction occurs in this region. The drugs could have their effect by shifting the dynamic equilibrium towards monomer. The existence of such an equilibrium state is a feature of other models of microtubule control in axons. For example, if microtubules are transported in the assembled state, they must be disassembled at the end of the axon. Should such an equilibrium exist, sufficiently high concentrations of drug not only might inhibit neurite extension but also cause net retraction. That outcome is reported by Bamberg et al. Thus, these data do not demonstrate microtubule assembly at the ends of axons. More direct experiments are required to demonstrate this reaction. FRANK SOLOMON

Disease gene relationship seen

SIR-A recent article by Royer-Pokora et al. described the isolation of a gene that is abnormal in the X-linked form of the phagocytic disorder chronic granulomatous disease (X-CGD), which is thought to be due to a lesion in the NADPH-oxidase system of these cells'. An unusual b-type cytochrome³ and a flavoprotein have been proposed as candidates for the polypeptide encoded by the Z-CGD locus, but the nucleotide

sequence of the cDNA clones isolated by Royer-Pokora et al. predicted a polypeptide that showed no significant homology to known sequences in the GENBANK or protein databases The authors could not identify any potential haem-binding region in the primary structure of the X-CGD protein.

We have, however, found a region of the predicted X-CGD sequence that is similar to the haem-binding region of the cytochrome P-450 proteins, and in particular to cytochrome P-450 form PBel from rabbit liver5. The figure below illustrates the point, and identifies with an asterisk the cysteine thiolare ligand to the haem prosthetic group of the cytochrome.

X-CGD protein LCGPEALAET Cytochrome P-450 V C*V G E A L A R M form PBc1

The haem-binding region is highly conserved among cytochromes P-450, some of which have only a slight overall sequence similarity to one another. It is of interest that the two regions are located at equivalent positions in X-CGD and cytochrome P-450 (at about amino acid 435).

Mankind's genetic bottleneck

SIR—Your correspondents question whether our interpretation of a small bottleneck in human evolution based on the patterns of distribution of β -globin haplotypes4 is correct and, if so, whether it is relevant to the origins of mankind. Our brief answer is that, although the modern distribution of these genes can in itself tell us rather little about where and how modern Homo sapiens originated, it is nevertheless the case that — given the assumptions of our very simple model and applying it only to β -globins -- passage through such a bottleneck is an inevitable implication of the present-day distribution of β -globin variants. We attempted to 'root' our evolutionary tree by reference to recent work on human fossils, which suggests that the most ancient H. sapiens are found in Africa. It is of course the case

that the geography of β -globin variants is in itself compatible with an African, an Asian or a dual origin of mankind, but the fossil record does seem to indicate an African birthplace for modern humans. As geneticists fallen amorig palaeontologists, we are not qualified to comment on the controversy as to the dating of African fossils, but have accepted the consensus view and used this (and not the β -globin tree) to suggest an African origin for mankind. Our deduction of a bottleneck at the origin of the rest of the world's human population is the simplest model consistent with the fossil data and the geography of the β -globins. Simplicity has forced us to make a number of assumptions.

One of these is that β -globin variants are selectively neutral. Nothing would delight us more than to learn that the possession of alternative haplotypes altered their carriers' ability to escape from sabretoothed tigers, but in the absence of evidence to the contrary we have accepted the view, implicit in most theories of molecular evolution, that natural selection does not act on noncoding sequences of DNA. As both your correspondents point out, this is not necessarily correct; and there certainly exist quite feasible modes of selection on noncoding variants by virtue of their linkage to strongly selected alleles such as that for sickle cell haemoglobin'. As there is simply no information on this possibility, we have, with Occam, chosen the more straightforward alternative. The model also includes the arbitrary; but simple, suggestion that the four commonest modern haplotypes were at equal frequencies in the ancestral African population. This assumption is not central to the existence of a bottleneck, but does influence its size. The frequencies in modern African populations pointed out by Giles and Ambrose could either reflect a conservation of their ancient values suggesting an even smaller bottleneck in the emergent population — or a change within Africa arising from genetic drift in small populations (which could be many times larger than our supposed bottleneck of emigrants).

Despite the widespread popularity among palaeontologists of models of a multiple origin of mankind (for example ref. 7 of Van Valen), theoretical population genetics suggests that any population's ability to undergo speciation is so limited that it is extremely unlikely that H. sapiens arose simultaneously in different parts of the world from different ancestors. For example, using a simple model of change by genetic drift, Sewall Wright showed in the 1940s that the probability of a chromosome rearrangement with a selective disadvantage to hybrids of 5% becoming established in a local population of 200 individuals is about 10 5 per generation. The chance of this happening simultaneously in two separate populations is about 10⁻¹⁰ per generation, which is extremely small, but may still be greater than the chance of simultaneous speciation in two separate populations. Van Valen's alternative suggestion — that of simultaneous global appearance of H. sapiens - implies extensive gene flow among its evolving populations, so extensive that both the ancestral H. erectus and the derived H. sapiens must be thought of as effectively sympatric. Sympatric speciation is itself difficult to accommodate into population genetics theory, and in Van Valen's scheme one is forced to explain the observed patterns of β -globin divergence by postulating long periods when large African and Eurasian populations of mankind were isolated from each other.

Our model, like many others, exists simply to show the evolutionary implications of an observed genetic structure. Its main point is to show that some of the demographic consequences of human gene frequency change are quite startling; startling enough, perhaps, to lead us to try to formulate a better model. A successful model would also, as we point out, have to explain why different genes seem to imply different demographic patterns during the spread of mankind.

Transfer of radioiodide to milk and its inhibition

SIR-Following the increased atmospheric levels of radioactivity resulting from the Chernobyl reactor accident, one of the main radiological concerns has been the entry of radioiodide into the human food chain through animal milk, and its subsequent uptake into the thyroid gland, as reported recently in your columns2

Current studies of transport mechanisms for various radionuclides in the mammary gland emphasize the rapidity with which blood-borne radioiodide can enter milk. The mammary gland of two goats was continuously infused for 15 min with 123 I (2.78 MBq; sodium iodide, AERE Harwell) through an indwelling polyvinyl chloride catheter placed in the external pudic (mammary) artery. Milk was completely removed by hand at 15 min intervals with oxytocin treatment (100 mUnits intravenously) and total radioactivity measured in a LKB Wallac 80000 gamma-sample counter. The total 123I activity secreted into the milk rose rapidly to a peak concentration just 30 min after the start of infusion followed by a slower

decrease. The fractional activity of 123I secreted in milk during a 2 h period was 1.0 and 1.5% of the infused activities.

The iodide concentrating activity of the mammary gland has long been recognized^{3,4}, and earlier work showed that the secretion of radioiodide into milk could be inhibited by competing anions such as perchlorate and thiocynate^{3,5}. We repeated the above experiment by infusing sodium perchlorate (100 mg) closearterially for 30 min before and during 123 I infusion. The total fractional 123I activity transferred into milk during 2 h was reduced by 60-66%.

Perchlorate has previously been found to be a more efficient inhibitor of radioiodide transfer into milk than thiocyanate, iodide or iodate³. Thiocyanate was not concentrated in rabbit milk3, but we are unaware of any data that quantifies perchlorate transfer into milk. This information is urgently needed before perchlorate administration could be considered as a means of protecting against the entry of radioiodide into the human food chain or into breast-fed infants after a reactor accident7. The use of perchlorate is not unprecedented since the compound has been used without deleterious effects in nuclear medicine to block, for example, the uptake of radionuclides into the maternal thyroid during diagnostic investigations. There is also a clear need to identify inhibitors which block mammary transport of other radionuclides, including fission products.

Our daily lead

Josef Eisinger

The Lead Debate: The Environment, Toxicology and Child Health. Edited by R. Lansdowne and W. Yule. Croom Helm: 1986. Pp.276. Hbk £25, Pbk £14.95.

LEAD may be, with the exception of 1 smoke, the oldest man-made environmental toxin. The manifold benefits which the element has bestowed on civilization - from plumbing to pigments - have been paid for heavily in human lives. Lead mining and manufacturing have of course been known as dangerous occupations since ancient times, but it was not until 1656 that Samuel Stockhausen, the first genuine occupational physician, presented clear evidence that lead was responsible for the particular ills and short life span of men and women engaged in these occupations.

Lead disease was, however, by no means confined to these and other lead workers. Lead was used as a wine additive

for many centuries (it is a bacteriocide and has a sweet taste), and inadequately fired leadglazed cooking utensils in 18thcentury Germany, were just two of many causes of widespread non-occupational plumbism. In contrast, massive chronic exposures are, in our own times, rare, but ingestion and inhalation of low levels of lead in the environment has become inescapable for all. As a result, the body burden of lead in modern man exceeds that of prehistoric

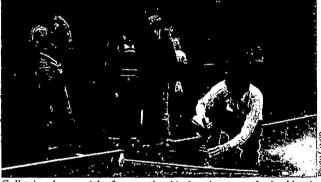

man by orders of magnitude. The leadsensitivity of different human enzyme systems varies greatly, however, so that the health effects of our lead environment are subtle, variable and often escape correct diagnosis. It is therefore not surprising that the toxicity of prevalent lead exposures presents a difficult problem and often provokes impassioined debates.

The Lead Debate is a multi-authored compendium of articles centered around the health effects of non-occupational lead exposure, particularly in children. It attempts to distil a vast amount of relevant information into a small volume, in order to make it accessible to a broad range of readers, including medical and social workers, environmental scientists and policy makers. The attempt is, except for some lapses noted below, successful.

The book is divided into three parts, of which the first deals adequately with the historical, chemical, geological and medical background of lead. Environmental lead disease is of course best controlled by limiting the amount of lead which industrial societies inject into air, water and | ZPP and PbB below that level, which is | lead, with particular emphasis on the

soil; and legislation which controls the amount of alkyl lead added to petrol represents a step in the right direction. The next line of defence against chronic exposure is clearly an effective screening programme for populations at risk, particularly for children, and the book includes a, regrettably, brief section on the methodology of measuring levels of lead in humans and in the environment.

The two screening methods which have been used more than any other are based on the concentration, in blood, of lead (PbB) and of zinc protoporphyrin (ZPP), respectively. The latter is a lead-induced, fluorescent metabolite which mimics the haem in haemoglobin during erythropoiesis and is most conveniently measured

Collecting dust particles from a school in London to test for lead levels.

by a dedicated, portable instrument called a haematofluorometer. Of these two assays, the ZPP assay is much cheaper, requires much less blood (generally a drop obtained by finger stick), provides an immediate result, and has a significantly higher correlation with the symptoms of chronic lead disease than PbB assays. For these reasons, the US Centers for Disease Control has recommended ZPP assays for the primary screening of children for lead poisoning and, incidentally, for iron deficiency anaemia. According to the Public Health Foundation, more than 700,000 such screening tests are performed by state health departments in the US each year; over 90 per cent of which use the ZPP haematofluorometer.

In light of this, it is strange that the chapter devoted to lead exposure measurements does not mention this instrument! It is even stranger that, despite its admitted advantages, the ZPP assay is "not recommended at blood lead levels of about '15 µg/dl". The reason given is that there is only a weak correlation between well within the range considered "normal" (< 25 µg/dl). Leaving aside the questionable relevance of this correlation, it is not clear why an efficient screening tool like the ZPP haematofluorometer should not be used to identify children with PbB levels above 15 µg/dl, for they have, without doubt, the greatest need for medical attention!

The second part of the book offers several well organized and informative chapters on the distribution and sources of lead exposure. Because they are written by only two authors, they avoid the unevenness of the earlier sections (where the references to primary sources are occasionally too sparse). Here one finds an account of, possibly, the most significant and elegant environmental lead study, in which the variation in the isotopic ratio (Pb206/Pb207) of the alkyl lead additives used in petrol was varied slowly over a period of six years. This variation was found to be closely linked to the isotopic ratio of airborne particulate lead as well as by the isotopic ratio of lead in the blood of subjects living in Turin and the surrounding countryside, where the experiment was

> conducted with the cooperation of Italian oil companies.

> This and similar studies in the US and UK have established that anthropogenic lead - principally from petrol combustion - is the most important component of lead pollution. Once it is injected into the air this lead finds its way into the human body, primarily by way of the food and water supply. Excessive concentrations in tap water have long haunted regions where lead pipes continue in use, as

for instance in Scotland. Reductions in the lead content of water have now been achieved by raising the pH of the water and buffering it with the aid of sodium hydroxide and inorganic phosphate additives.

In the UK and the US, the most serious cases of lead poisoning in children can be traced to lead-pica - the chewing of either peeling paint or of painted articles. prompted by the sweet taste of the lead ion (Pb2+). (The term pica is derived from the much maligned magpie, Pica pica.) The strategy for prevention is clear: removal of old paints and the use of nonlead paints for interior surfaces. What the book's authors fail to mention is that well-meaning government regulations are, because of their enormous cost, rarely enforced, so that effective screening programmes for young children again offer the best hope for finding and eliminating trouble spots and for providing needed medical attention.

The remainder of the The Lead Debate addresses the health effects of ingested

psychological development of children exposed to ordinary environmental lead levels. It opens, appropriately enough, with a discussion of the methodological difficulties of interpreting the numerous studies which attempt to identify the disease-exposure relationship. It is unfortunate that most of these studies use PbB as the only exposure index, although the most important study in America does include dentine lead as a cummulative index. The warning against equating correlations with causal relationships are well taken, and the critical commentary on the conclusions drawn from studies exploring lead-effects on intelligence and behaviour are particularly helpful. Although caution in the interpretation of low-level exposure data is clearly in order, there is no lack of evidence, from epidemiological studies and animal experiments, that massive and moderate exposure produces measurable neurobehavioural effects.

The enduring dilemma surrounding the lead debate is that the threshold of leadrelated disease continues to defy definition. This should surprise no one for it requires a quantitative determination of such multivariate parameters as intelligence, behaviour and learning. But supposing that such a threshold could be translated into an indicator of exposure (for example PbB or ZPP levels, vide supra) a second, even more difficult question faces policy makers; what is the fiscal value which society attaches to the elimination of marginal plumbism? In crasser terms, how much is the taxpayer willing to pay, in order to raise the average intelligence of the population by, say, 1 per-

It is unfortunate that these tricky issues are rarely touched upon in *The Lead Debate*. Usually, the authors prefer to remain on the safe technical level and to quote from general conclusions of governmental commission reports. A chapter on real and perceived risk of lead disease compared to other health insults which we are exposed to, together with estimates of their cost of abatement, would have been welcome (c.f. *New England Journal of Medicine* 1982:1392).

On the other hand, the contributors have collected a lot of extremely useful scientific information which will undoubtedly help to keep the continuing debate about plumbism on a firm scientific footing. They have succeeded in avoiding polemics, albeit at the cost of avoiding novel or controversial approaches. Nevertheless *The Lead Debate* is an important and useful interdisciplinary review of where we stand in our efforts to unravel the complexities of this ancient environmental hazard.

Visitors from the past

Theya Molleson

Lindow Man: The Body in the Bog. Edited by I.M. Stead, J.B. Bourke and Don Brothwell. British Museum Publications, London: 1986. Pp.208: £15.

The great interest that attaches to any bog body derives not simply from the rarity of such finds but also from the intrinsic nature of the body: it is almost a visitor from the past. Such bodies should tell us more of the life and character of the earlier people. To deduce the age and sex of a body is one thing; but to know something of his clothing and ornaments and to discover the ingredients of his last meal and, above all, to see his face is somehow to perceive the whole anima of his time. I don't think that we should be disappoin-

one of the most significant bog findings in Britain and the greatest challenge to archaeological conservation. Within days the police moved out, the hospital wanted the body removed and the conservationists were asked to take over. They were expected to prevent any deterioration of the body while allowing endless study, photography, sampling and dissection. And all they knew from previous experience was what *not* to do. By a conscientious and didactic approach it does seem that Lindow Man has been preserved for posterity.

The volume, Lindow Man, presents the progress reports of the wide range of exploratory studies — from identification of the surrounding peat and of the pollen, cereals and parasites in the stomach to interpretation of the context both geographic and cultural. Some papers are too clearly hurriedly written; others tend to be discursive for want of factual evidence. It is surprising how little appears to be known of our Celtic heritage.

Lindow Man has his back cleaned, taken from The Bog Man and the Archaeology of People (British Museum Publications, Pbk £5.95). In this book, Don Brothwell gives a briefer, less technical account of the Lindow project. Lindow Man is also on display at the British Museum in London, together with the results of the research programme, as part of the exhibition Archaeology in Britain which runs until 15 February 1987.

ted when our expectations are but inadequately realised. Lindow Man has been thoroughly studied but has yet to tell his full story and, not least, to declare his age.

Enormous credit must go to Rick Turner, the county archaeologist for Cheshire, where Lindow Man was discovered in 1984. He was able immediately to appreciate the archaeological potential that lay in just a fold of skin exposed in the section at the peat cutting. He even managed to convince all concerned that the correct procedure then was to delimit the area of the body, if body there was; to cut it out and crate it for removal to the local mortuary. At this stage the investigation was still a police matter, and not

Concepts of sacrificial ritual emanating from the bog finds in Europe have dominated the approach to the study of Lindow Man. Several workers have found it hard to view their data independently of these theories so that the final interpretation tends to be prejudiced. Yet the information as presented is open to other constructs than that of a ritual killing on the lines of the Danish Bog burials. And that is the advantage of the presentation of the independent studies in detail and in one volume. Readers can make up their own minds.

Dial a vector

Tim Harris

Cloning Vectors: A Laboratory Manual. Edited by P.H. Pouwels, B.E. Enger-Valk and W.J. Brammar. Elsvier:1985. Approximately 400 sheets in Loose-leaf binder. \$55, Dfl. 160.

LABORATORY manuals have become a popular means of disseminating the complicated protocols of modern molecular genetics, the best example being Molecular Cloning — A Laboratory Manual, referred to by some as the cloning bible, by Maniatis et al. Some of these manuals, like the above, combine theory with practice while others are simply sophisticated recipe books. Although described as a laboratory manual, Cloning Vectors is a directory of the vectors currently available for introducing genes into a variety of organisms. The vital statistics of some 300 vectors, both plasmid and phage in origin, are described by means of clear, singlepage diagrams. About one-third of the plasmids are those used for the most commonly employed cloning host — the gram negative bacterium E. coli. The remaining chapters cover vectors for gram positive bacteria (for example, Streptomyces), fungi (including yeast) and plant and animal cells.

The work is comprehensive, as up to date as might be expected in a fast-moving field, and the clarity and simplicity of the figures is impressive. Provided you know what you are looking for, the salient facts are easy to obtain. It is possible to use the summary tables at the end of each chapter to locate vectors with desired characteristics (one of the objectives of the book) but it's a pity little attempt was made to rank or distinguish commonly used vectors from more esoteric and not necessarily more useful ones. The loose-leaf format of the directory is designed so that annual updates can be included; some of the newer cosmid vectors for genome walking and vectors for insect cell expression can be expected*.

The lack of theoretical back up — the introductions to each chapter are only one or two pages — indicates that this book is not intended for the individual graduate or postdoctoral molecular biologist. Rather, like a telephone directory, it is a reference book that every genetic engineering lab will want access to, be it on their library, laboratory or office shelf.

*These are indeed included in the first update which will be available in September. Price \$20, Dfl. 60. Orders for the main manual plus three annual updates are entitled to the reduced price of \$97.75, Dfl. 287.

History isn't bunk

John H. Lawton

Modeling Nature. Episodes in the History of Population Ecology. By Sharon E. Kingsland. University of Chicago Press: 1985. Pp.267. \$27.50, £23.50.

As every schoolboy knows, Henry Ford thought that history was bunk, a view that is certainly common, if not universally held by many creative and successful scientists about their own subject. There is, after all, too much to read about what is happening today to care about what happened yesterday, still less about events 50 or more years ago. But a sense of perspective is no bad thing in any walk of life, and science is no exception, as Sharon Kingsland's book makes plain.

The book is a detailed history of the rise of population ecology from its early beginnings in the writings of Frederic Clements and Stephen Forbes (who in turn drew their inspiration from Charles Darwin, Herbert Spencer and so on, but historians have to stop going backwards somewhere), through Alfred Lotka, Raymond Pearl and Vito Volterra, and from there on a direct intellectual route via Georgii Gause to Evelyn Hutchinson, David Lack and Robert MacArthur. There were, of course, other contributors, some major some minor, but this pedigree is particularly clearly defined, and gives a good indication of the scope of the book, and the time-scale involved.

Reviewing books is often a chore, is usually educative, but is only infrequently a real pleasure. Modeling Nature unfolds like a good detective story, and is a delight to read for at least two reasons. It is a beautifully written, well-crafted account of a complex subject; although I thought I knew the roots to population ecology fairly well, I found that many of my ideas were either fuzzy or wrong. It is extremely useful to have the key intellectual advances so clearly laid out. Second, and probably more important, the book is about people as well as ideas. It was, after all, no lesser historian than Edward Gibbon who said that history is "little more than a register of the crimes, follies, and misfortunes of mankind"! One would hesitate to use quite these terms to describe the history of population biology. but the founding fathers were not modest angels. They were certainly clever, but they were also - in varying degrees opinionated, scheming and paranoid, as well as insightful, helpful and wise. And all of them were men, which in itself is an interesting comment on the sociology of science, although Kingsland does not open this particular can of worms.

Population ecology is currently in the throes of a series of intense and, at times, acrimonious debates. The arguments have several overlapping strands, including the role of density-dependent processes in population regulation, the importance of interspecific competition in structuring communities, the value of mathematics in ecology, and the proper way of doing science that would solve all these problems if only everybody would adopt the true way. Not one of these problems is new. All have been debated with just as much ferocity in the past, and what history shows is that the entrenched positions of the principal assailants have almost always proved to be misguided, irrelevant or wrong. History isn't bunk; it gives a sense of proportion.

Confronted with the realisation that we have been here before, sometimes more than once, it is easy to believe that population ecology has simply wandered round in aggressive circles, getting nowhere since Lotka published Elements of Physical Biology in 1925 and Volterra his famous letter to Nature a year later. Nothing could be further from the truth. Population and community ecology have made great strides over the past 60 years, despite the complexities of natural communities. From the fires of strong disagreement ultimately emerges the phoenix of scientific progress. But a better sense of history might reduce the sparks currently flying round population ecology, and help to generate less heat, more light and greater tolerance.

Plants in distress

Richard Dixon

The Biochemistry and Physiology of Plant Disease. By Robert N. Goodman, Zoltán Király and K.R. Wood. *University of Missouri Press:1986. Pp.433.* \$45.

RESEARCH in plant pathology is now entering an exciting period. Pathologists are becoming increasingly aware of the potential of new molecular techniques, while plant biochemists and molecular biologists are showing corresponding interest in plant-pathogen interactions as important systems for studies of cellular recognition, metabolic integration and gene expression. Any new, comprehensive review of this field should be judged in terms of its success in presenting the bases (often multidisciplinary) of current concepts, and its exposition of new experimental approaches. My first impressions of The Biochemistry and Physiology of Plant Disease were of a magnum opus, among whose wealth of detail would surely be found the signposts to future research. A full reading of the book left me impressed by the scale of the authors' understanding, but somewhat disappointed by the book's lack of direction and its conclusions.

Most chapters consist of brief descriptions of the biochemistry or physiology of a particular aspect of the healthy plant (respiration, photosynthesis, cell walls and so on) followed by detailed analyses of the effects of infection under the separate headings of viruses, bacteria and fungi. Taken together, the introductory sections almost make up a basic plant bio-

chemistry text, good in some sections (particularly cell walls), but in others too condensed to be of much value to non-biochemists (for example, the glyoxylate cycle is presented with no mention of its role in metabolism). Although the conceptual aspects are presented critically and lucidly, there are a relatively large number of material inaccuracies, particularly in the introductory biochemical sections — tyrosine is not only found in the *Gramineae* (p.211), acetyl CoA units are certainly not condensed to yield malonyl CoA (p.212) and phenylalanine is not altered by hydrolases (p.226).

The organization of the material, based on physiological divisions rather than temporal sequences of events, has inevitably led to repetition of information under different headings, although this is less apparent in the sections on viruses. Such repetition in a long work is often no bad thing, but some important topics are never fully dealt with in one section and appear piecemeal throughout the book. The accounts of the *Agrobacterium* system, fungal and host elicitors, and induced host gene expression fall into this category.

The scope of the book is, of course, clear from its title, and the depth of treatment and excellence of the illustrations will no doubt ensure its success as a standard text for advanced students. I was, however, disappointed by the lack of attention to genetics, both classical and molecular (viral nucleic acid metabolism excluded), as it is from the application of recombinant DNA techniques that the most promising developments in plant pathology will probably arise. In this respect, I feel that the authors' honestlyconfessed lack of agreement in several areas, particularly the molecular basis of disease resistance, rather robs the book of an important component — that of informed prediction, even if based on personal prejudice. The search for avirulence, virulence and resistance genes is now a central effort in plant pathology, and more speculation in these areas, at the expense of repetition of correlative phenomena reviewed earlier in the book, would have increased the impact of the final "rounding-off" chapter on disease resistance. Likewise, the concluding sections to the individual chapters, each headed "Comparative Analysis of Disease Physiology", simply summarize rather than integrate the views of the individual authors.

Such problems apart, it is perhaps unfair to criticize the book too much for what it does not cover. It stands as a detailed source of information on physiological plant pathology, one which will certainly be widely read.

Baking and brewing in Egypt around 2400 BC, taken from the Open University study pack on Biotechnology (PS621, £119). Designed for those with no specialist knowledge, the pack consists of over 600 pages of text divided between eight books, including two volumes Laboratory to Marketplace which look at the impact of biotechnology on a number of key industries, a series of case studies and two books of supporting technical material. Although the modular pack is designed to be free-standing, there is an associated set of six video tapes (£115 each or £299 for the set). Available from Learning Materials Sales Office, The Open University, PO Box 188, Milton Keynes MK7 6DH, UK.

Aleutian terranes from Nd isotopes

R. W. Kay*†, J. L. Rubenstone‡ & S. Mahlburg Kay*

* Institute for the Study of the Continents (INSTOC), and † Department of Geological Sciences, Cornell University, Ithaca, New York 14853, USA ‡ Lamont-Doherty Geological Observatory, Palisades, New York 10964, USA

Nd isotope ratios substantiate the identification of oceanic crustal terranes within the continental crustal basement of the Aleutian island arc. The oceanic terranes are exposed in the westernmost Aleutians, but to the east, they are completely buried by isotopically distinct arc-volcanic rocks. Analogous oceanic terranes may be important components of the terrane collages that comprise the continents.

CONTINENTAL crust is a mosaic of structurally coherent terranes. Palaeomagnetic investigations have revealed that the terranes often originated within ocean basins, or at their margins, and travelled great distances before 'docking' at continental margins. The crust of the Aleutian island arc is analogous to that of many of these far-travelled terranes, and yet is simpler in structure, having not yet experienced the deformation and metamorphism which accompany terrane suturing. The Aleutian crustal building blocks are terranes themselves, and include oceanic crust, back-arc crust and subduction-related arc magmas. We show here that Nd isotope ratios are remarkably successful in identifying Aleutian terranes. We then define the lateral and vertical variations in Aleutian crustal architecture, and contrast a cross-section of oceanic (back-arc)-dominated crust in the western Aleutians with our previously documented¹ arc-magma-dominated crust in the eastern Aleutians.

Recent volcanic rocks

As a starting point, we note the isotopic homogeneity of Nd $(\varepsilon_{\rm Nd} = 7.30 \pm 1.25$; see Table 1 for definition) in a wide compositional spectrum of recent Aleutian volcanic rocks (see Figs 1, 2). This isotopic monotony contrasts with the distinctive chemical and mineralogical trends developed during the magmatic evolution of the volcanic rocks^{2,3}. Although there is no agreement as to how the Nd isotopic homogeneity was acquired⁴⁻⁸, for the present purpose it is more important to establish that the narrow range of ε_{Nd} that characterizes magmatically evolved Aleutian lavas was not acquired in the crust. To establish this we show that the same narrow range extends to minerals that have fractionated at depth from primitive (mantle-derived) magmas. For example, voluminous pyroclastic flows from Moffett volcano, Adak island, central Aleutians (Fig. 1), contain cumulate-textured xenoliths of mafic and ultramafic composition⁹. The xenoliths are mid-crustal crystalline wall rocks of dykes that carried the magmas to the surface. The xenoliths represent magma compositions ranging from olivine tholeiite (capable of precipitating Ni-rich ölivine, Cr-rich clinopyroxene and Cr-rich amphibole, the cumulate minerals of xenolith MM76-102)9 to andesite (capable of precipitating clinopyroxene, amphibole and plagioclase, the cumulate minerals of the least magnesian xenolith, MM76-10)9. Nd isotope ratios of three of these xenoliths and the host andesite are the same (Table 1); thus ϵ_{Nd} is independent of crustal-level fractionation processes, and is characteristic of mantle-derived arc magmas. 10 Be, a cosmogenic nuclide (half-life 1.5 Myr) which is present in young volcanic rocks of the arc, is also present in the most mafic of the xenoliths, MM76-102¹⁰ (the only Moffett xenolith analysed so far). From the standpoint of tectonics, an Aleutian cross-section would include these volcanic and plutonic rocks in the same terrane.

As a second example, ultramafic (olivine-clinopyroxene) xenoliths from Moffett's sister volcano Adagdak (see Fig. 1) are

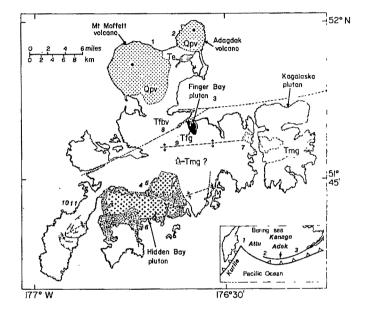

Fig. 1 Generalized geological map of Adak island⁴⁰, in the Central Aleutian island arc. For the Hidden Bay pluton, distribution of more silicic (>60% SiO₂, 'granodiorite') interior and less silicic (<60% SiO₂ 'diorite') exterior is after ref. 41. The plutons intrude the Finger Bay Volcanics (areas with no symbol on the map). Adak xenolith localities are Mt Moffett (51°58.01′ N, 176°43.55′ W, locality 1) and Mt Adagdak (51°58.78′ N, 176°37.36′ W, locality 2). These and numbers 3-11 refer to the location of samples listed in Table 1. The generalized inset map shows the locations of Attu, Kanaga and Adak islands and of the Komandorski back-arc basin (1), Amchitka Island (2) and Unalaska Island (3). Tooth marks indicate the trench segments that have associated active volcanoes.

ductilely deformed tectonites 9,11 . The $\varepsilon_{\rm Nd}$ values of one of these tectonites is +7.2 (Table 1), and it contains small amounts of ¹⁰Be (ref. 10). Thus, we infer that the tectonites are geochemically related to the magmas of the recent volcanoes. On a tectonic cross-section, we infer that the deformation (which by textural arguments occurred at high temperature) is recent, and thus represents an active tectonic feature of the arc. We have proposed^{1,11,12} that the rocks are early-stage cumulates of arc magmas that reside in the sub-arc asthenosphere, which extends to depths as shallow as the Moho under the present arc. Stated in tectonic language, the brittle-ductile transition has reached shallow (Moho) levels directly under the Aleutian arc (see Fig. 3a). Note that the ε_{Nd} values for recent Aleutian volcanic rocks are higher than those for many other arcs with older continental basement, and apparently these high values extend to the Kurile Arc, based on two analyses (Table 1) which are within the narrow range of the Aleutian values.

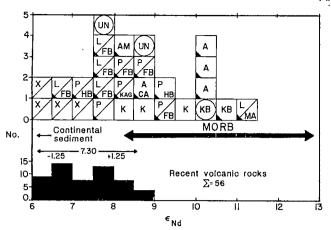

Fig. 2 Histogram of ε_{Nd} values of Aleutian volcanic and plutonic rocks^{18,24}, plotted relative to a BCR-1 ε_{Nd} value of -0.4 (ref. 7). \square , Adak: L, lava (FB, Finger Bay; MA, magnesian andesite); X, xenolith; P, pluton (KAG, Kagalaska; HB, Hidden Bay; FB, Finger Bay). K, Kanaga xenoliths; AM, Amchitka pluton; \square , Unalaska pluton; A, Attu (CA, calc-alkaline); KB, Kamchatka basin. L, LDGO; \square , literature. Recent volcanic rocks $6^{-8,14,15,24,42,43}$, mid-ocean-ridge basalts (MORB)^{30,31}, Unalaska pluton (Captains Bay, ref. 24) and Komandorski basin basalt are all from the literature. (Other analyses, including an independent analysis of the Komandorski basin basalt, are listed in Table 1.) Note the coincidence of: (1) Attu island lavas and Komandorski basin basalt; (2) Finger Bay lavas (early Tertiary) and 56 Recent volcanic rocks; (3) Adak xenoliths (from Moffett and Adagdak volcanoes) and Recent volcanic rocks plot between recent volcanic rocks and the Attu-Komandorski basin lavas. We interpret the rocks with intermediate ε_{Nd} as geochemical hybrids.

A singular lava

It has been known for some time that lavas of the Aleutian arc have variable Sr and Pb isotopic compositions 13,14 . The most isotopically extreme lava comes from a thick, magnesian andesite flow or sill at the base of Mt Moffett (Fig. 1). It has very non-radiogenic Sr and Pb (ref. 14) and very radiogenic Nd ($\varepsilon_{\rm Nd} = +11.3$ (ref. 15; see Table 1), a value which is at the high end of the mid-ocean-ridge basalt (MORB) range (Fig. 2)). This lava also differs in its trace element content from all other Aleutian lavas analysed so far 14. We infer that a region under the main volcanic arc, but at unknown depth, has MORB-like character. Some possibilities are: the subducted oceanic crust (but without isotopic or trace element contamination from hydrothermal alteration by sea water), the overlying asthenosphere, or even, as we will see, the crustal or mantle lithosphere.

Older magmatic rocks

The magmatic history of the Aleutian arc reaches back to the early Tertiary¹⁶⁻¹⁹. On Adak island, the early volcanic and volcaniclastic rock units, mapped as the Finger Bay Volcanics (Fig. 1), are cut by plutons of several ages. On the westernmost Aleutian Islands (Attu and the other Near Islands) and the Komandorski Islands there are no active volcanoes (plate motion up to ~5 Myr ago was nearly strike-slip)20, but there are excellent exposed sections of Tertiary volcanic rocks, cut by intrusives 18,21. Isotopic contrasts between the Tertiary lavas of Adak and Attu¹⁸ constitute our first indication that the Aleutian arc crust is not comprised entirely of arc magmas of the type that are erupting today. The early Tertiary (40Ar/39Ar crystallization ages >50 Myr¹⁸) Finger Bay volcanics from Adak have the same ε_{Nd} as recent Aleutian volcanic rocks (see Fig. 2). In contrast, the earliest volcanic rocks on Attu (probably 20-30 Myr in age)¹⁸ have higher ε_{Nd} (well within the range of mid-ocean-ridge or back-arc-basin basalt; see Fig. 2) than any magmatic rocks of any age in the arc (except, as always, the

Mg-andesite from Adak). However, not all Attu lavas have high $\varepsilon_{\rm Nd}$. A hornblende andesite representing the volumetrically minor, youngest (Miocene) volcanic rocks on Attu has ε_{Nd} that is in the range (within error) of values of recent volcanic rocks. These data from Attu can be explained either by evolution of magmas from high to low ε_{Nd} during the Tertiary, or by an origin of the earliest Attu magmas in a back-arc setting. A third alternative, origin at a mid-ocean ridge, is not consistent with recent syntheses of the plate kinematics of the North Pacific^{22,23}. The apparent invariance of ε_{Nd} with age over the same time period (30 Myr) on Adak and Unalaska^{18,24} (an eastern Aleutian island; see Fig. 1) argues against isotopic evolution of the arc from high to low ε_{Nd} (ref. 7). The similarity of the oldest Attu lavas and a Miocene back-arc lava from the Komandorski basin (Table 1), not only in ε_{Nd} but in Sr isotope ratio⁷ and a wide range of lithophile elements (in particular, the rare earths)¹⁸ supports our proposal that the Attu section represents lavas and interbedded cherts and turbidites from a back-arc basin analogous to the younger Komandorski basin. Subsequently, these 'basement' rocks were intruded by subduction-related dykes, and in places they are overlain by basaltic and andesitic lavas fed by the dykes, but this arc-related magmatism is minor in volume.

Some units of plutons that intrude the Finger Bay Volcanics on Adak (see Fig. 1) have $\varepsilon_{\rm Nd}$ values which are slightly higher than those of the highest- $\varepsilon_{\rm Nd}$ volcanic rocks (see Fig. 2). Within both the Hidden Bay and Finger Bay pluton it is the most mafic samples (the gabbros) that have these high $\varepsilon_{\rm Nd}$ values. McCulloch and Perfit's²⁴ analyses of an Unalaska pluton show the same trend. The variability within the plutons indicates a heterogenous source, or mixing of igneous rocks from more than one source. It is somewhat perplexing that the most mafic lavas do not show this tendency towards high $\varepsilon_{\rm Nd}$. We believe that this is the first indication that the volcanic and plutonic rocks are petrogenetically distinct. We tentatively identify the high- $\varepsilon_{\rm Nd}$ end-member as oceanic crust buried within the arc crust.

Crustal and mantle tectonites

A remote cluster of later Tertiary basaltic intrusives on the magmatically inactive southern part of Kanaga Island (~30 km west of Adak) has yielded mafic and ultramafic xenoliths which contrast strongly with those from Adak (discussed above). To the previously documented mineralogical contrasts²⁵⁻²⁹, most obviously the fact that they are amphibole-free, unlike their Adak counterparts, we now add a contrast in ε_{Nd} . Both mafic and ultramafic tectonites have higher ε_{Nd} than the Adak cumulate and tectonite xenoliths. The highest value ($\varepsilon_{Nd} = +9.6$) lies well outside the range of Aleutian lavas, and within the range of both mid-ocean-ridge and back-arc-basin basalts30,31. But the xenoliths are clearly not pieces of the subducted oceanic plate (from 100 km depth), for their mineralogy indicates equilibration at much shallower depths, within the spinel lherzolite stability field or shallower (for the plagioclase-bearing but garnet-free mafic granulites) We have proposed that the xenoliths originated as buried pieces of oceanic or back-arc lithosphere. They have been almost completely recrystallized and therefore retain few textural or mineralogical clues to their origin. They also appear to be hybrids: they are geochemically intermediate between arc and MORB types. Assimilation of some of this hybridized lithosphere by arc magmas may account for the unusually high ε_{Nd} of some of the plutons, noted above.

By analogy, this interpretation finds some support in a study of ophiolites. In the Troodos ophiolite³¹, a range of ε_{Nd} values can be interpreted as reflecting two-component mixing (although at a depth greater than that envisioned here) between a MORB-like ($\varepsilon_{Nd} \ge +8$) and a continental-crustal (ε_{Nd} negative) source. The Sr isotopic composition of the Troodos ophiolite rocks varies widely (87 Sr/ 86 Sr ranges from 0.70415 to 0.70705), and is independent of the Nd isotopic values. Much the same can be

said for the Samail ophiolite³⁰, but with much smaller ε_{Nd} variation, and for the Kanaga xenoliths and the older Attu volcanic rocks (Table 1).

Tectonic cross-sections

The brief (55 Myr)^{18,19} history of the Aleutian island arc records the juxtaposition of several geochemically distinct terranes: oceanic and back-arc lithosphere occurring either at the surface (Attu) or buried under younger arc magmas (Kanaga); continent-derived sediment, with $\varepsilon_{\rm Nd}$ values near zero⁷, retained within the arc crust or added to it by off-scraping or subcretion^{32,33}; and subduction-related magmas intruded along an arc axis which has migrated northward during the Tertiary (see Fig. 1). The proportion of these terranes varies along the arc: a western Aleutian cross-section (near Attu) will have a higher proportion of oceanic lithosphere than one through the central Aleutians (near Adak). Further east, along the Alaska Peninsula we expect additional terranes, including isotopically distinct older continental crust and exotic lithospheric fragments carried

from far to the south³⁴. Sediment draping the flanks of the arc contains a variable proportion of erupted and eroded arc material representing the exposed terranes.

Figure 3a is a tectonic cross-section of the central Aleutian arc¹, which applies more specifically to the Adak-Kanaga region. A second section (Fig. 3b), representing the Attu region (consistent with shallow, thrust-mechanism seismicity, Fig. 3c)^{35,36} looks quite different. Here, we postulate that structural thickening of the crust by nearly arc-parallel thrusting is necessary to elevate the back-arc oceanic crust now exposed at the surface. We find very little arc-related magmatism that could build the crust up from abyssal depth to sea level over the past 30 Myr.

Note, in Fig. 3a, that the oceanic or back-arc crustal section (and in particular the sediment associated with it) is completely recrystallized during arc-related deformation and heating. It has also been intruded by arc magmas (it was an arc magma that carried xenoliths of the section to the Earth's surface on Kanaga island). The arc magmas have variably contaminated the

[†] C, CIT; L, LDGO. Analytical procedures are described in refs 7 (CIT) and 15 (LDGO). Sr and Nd isotope analyses were performed in the same laboratory.

[†] $\varepsilon_{Nd} = [((^{143}Nd/^{144}Nd)_{sample (t)}/(^{143}Nd/^{144}Nd)_{bulk Earth (t)}) - 1] \times 10^4$. For all analyses, ε_{Nd} of BCR-1 standard was taken to be -0.4, measured $^{143}Nd/^{144}Nd$ values were: CIT, 0.511826; LDGO, 0.512645. Direct comparison of samples: DSDP191, CIT, +10.2; LDGO, +10.6. For both CIT and LDGO, $^{87}Sr/^{86}Sr$ was normalized to $^{86}Sr/^{88}Sr = 0.1194$.

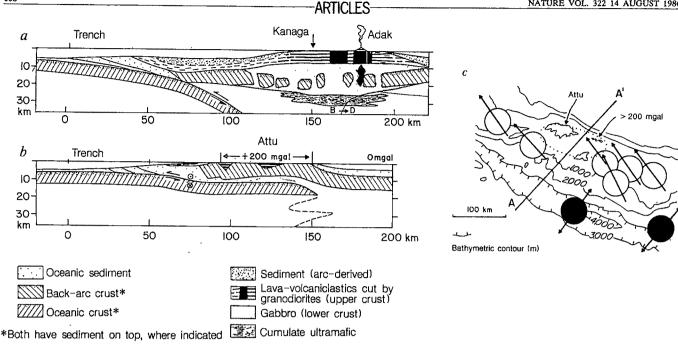

Fig. 3 a, b, Tectonic cross-sections of the central and western Aleutian arc (no vertical exaggeration). a, Section in the region of Adak and Kanaga (Fig. 1); near-surface tectonic features are after refs 44-46. Oceanic terranes are represented by symbols on the left, subduction-related terranes by those on the right. Geometry of lower-crustal terranes after ref. 1. Projected positions of Adak and Kanaga xenolith localities are shown, as is the present position of the brittle-ductile transition (B + D). Migration of the brittle-ductile transition away from the trench in the Tertiary is inferred from the deformation of mantle and lower crustal xenoliths from Kanaga island. b, Cross-section along A-A' in map c. Crustal imbrication is inferred from earthquake mechanisms, from the paucity of arc-related igneous rocks, and from the extensive sections of back-arc-related volcanic rocks exposed on the surface of the islands. c, Map view of Attu region, showing earthquake mechanisms 35,36 and extent of +200 mgal free-air gravity anomaly³⁷.

xenoliths (and the deep crust of the arc), yet not to the extent of erasing their Nd isotope signature. From textural studies, it appears that some mineralogical vestiges of a pre-contamination condition exist²⁶⁻²⁹.

How much crustal contamination of arc magmas by buried hydrothermally altered oceanic crust (including sediment) occurs? We may speculate that water makes melting relatively easy and that the buried oceanic crust should contribute disproportionately to the arc magma contamination. The constant $\varepsilon_{\mathrm{Nd}}$ (and ⁸⁷Sr/⁸⁶Sr) of the Moffett cumulate-textured xenoliths (see Table 1) is important in this context, for with contamination, $\varepsilon_{\rm Nd}$ and $^{87}{\rm Sr}/^{86}{\rm Sr}$ should be dependent on fractionation stage (as they apparently are for the plutons). Despite our published opinion to the contrary4,14, we suggest that the trapped oceanic crust may melt to yield the enigmatic, high-ε_{Nd} Mg-andesites, and may yield a high- ε_{Nd} component for Tertiary plutons.

In Fig. 3b, we correlate the shallow, thrust-mechanism earthquakes^{35,36} (Fig. 3c) with oblique intracrustal thrusting (parallel to the trench). We have indicated intracrustal thrusting at the interfaces between imbricated oceanic and back-arc crustal sections. These interfaces will act as strain guides, because of the presence of both water (hydrothermal alteration) and sediment. The interfaces are also the likely intrusion sites for the small amounts of arc-related intrusives. Shallow structural imbrication of oceanic and back-arc crust, (perhaps including oceanic plateaus) is consistent with a +200 mgal free-air gravity anomaly and the high gravity gradient in the region³⁷. Note that immediately west of Attu, the arc crust is very much thinner and deeper. In our interpretation, Attu represents a structural culmination of arc-parallel oblique thrusting.

Discussion

The identification of geochemically coherent terranes within the Aleutian arc lithosphere provides a rational and useful framework for consideration of the chemical controls on arc tectonics ('chemotectonics'). The creation of mixed terranes by erosion and magmatic assimilation should also be well described within this framework, as should the comparison of the Aleutians and other arcs. The structural response of various levels in the arc lithosphere to the stress regimes within a convergent plate margin will be controlled by water, and to a lesser degree by rock type within the arc crust. We note specifically the potential role of trapped hydrothermally altered oceanic crust at midcrustal levels and its potential role as a strain guide (see Fig. 3b). This makes plausible the coincidence of major geochemical and tectonic boundaries within the arc crust.

We thank G. J. Wasserburg for hospitality and access to the Lunatic Asylum, and A. Zindler for access to the LDGO isotope laboratory. H. Ngo assisted R.W.K. at CIT. Research support is from NSF (R.W.K., S.M.K., G.J.W., A. Zindler) and NASA (G.J.W.). This is INSTOC contribution 45.

Bovine papillomavirus genome elicits skin tumours in transgenic mice

Mark Lacey, Susan Alpert & Douglas Hanahan

Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724, USA

Transmission of the bovine papillomavirus-1 (BPV-1) genome through the mouse germ line results in the heritable formation of fibropapillomas of the skin, a tissue-specific phenotype analogous to that observed in natural BPV-1 infection of cattle. Oncogenesis is slow, with tumours first arising at 8-9 months of age, usually in areas prone to wounding. Extrachromosomal BPV-1 DNA is detected in all tumours, whereas normal tissues show only integrated DNA.

BOVINE papillomavirus 1 (BPV-1) is an icosahedral virus which infects cutaneous tissues of cattle and induces benign fibropapillomas with proliferative squamous epithelial and dermal fibroblast components^{1,2}. The BPV-1 genome is circular doublestranded DNA of ~8 kilobases (kb). The virus infects both dermal fibroblasts and epidermal epithelial cells, where the BPV-1 genome replicates as an autonomous plasmid, inducing proliferation of both cell types. Virus particles are produced only in terminally differentiated epidermal keratinocytes, where the BPV-1 DNA replicates to a very high copy number (about. 10,000 copies per cell). In contrast, the copy numbers range from 50 to 500 per cell in the proliferating dermal fibroblasts and in the squamous epithelial cells of the lower epidermis. BPV-1 shows a broad experimental host range; it has been shown to infect horses, hamsters and one inbred strain of mouse (C3H_eB). Infection of these heterologous species results in the development of fibroblastic tumours, generally at the site of infection/inoculation, but without the subsequent production of infectious virus particles.

The genetics of BPV-1 replication and transformation have been studied principally in cultured murine cells^{1,2}. BPV-1 replicates as a stable extrachromosomal element in a variety of cultured mouse fibroblasts, and is able to morphologically transform a cell line (C127) derived from a murine mammary tumour. as well as NIH 3T3 cells. The necessary cis- and trans-acting elements for both transformation and replication have been localized to a fragment which comprises 69% of the viral genome, given that the genetic assay is restricted to a few established cell lines.

In the present study we have sought to address the properties of the BVP-1 genome when transmitted through the mouse germ line, in order to assess the ability of BPV to replicate in and transform murine cells in the context of its stable presence in every cell of the animal.

Generation of transgenic mice

The bovine papillomavirus genome was injected into fertilized mouse embryos as a SalI-linearized plasmid clone, which is shown in Fig. 1. The plasmid (called pBPV1.69) carries a partial tandem duplication of the complete BPV-1 genome. This configuration was used for two reasons: first, to provide an

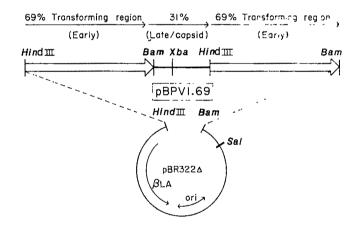

Fig. 1 Structure of the plasmid pBPV1.69. Two copies of the 69% transforming region (HindIII-Bam) of BPV-1 are separated by the 31% 'late' region, thereby generating a reiterated copy of the intact BPV-1 genome-a 100% fragment plus an additional copy of the 69% transforming region.

Methods. The plasmid pBV1.69 was linearized by digestion with Sall, purified by phenol and chloroform/isoamyl alcohol extraction, and ethanol precipitation. The concentration was adjusted to ~1,000 ng ml⁻¹ before injection into fertilized one-cell embryos, which were implanted into pseudopregnant female mice and allowed to develop. The embryos were derived from intercrosses of (C57BL/6J \times DBA/2J) F_1 hybrid mice, and thus were F_2 hybrids The one transgenic mouse (M120) which survived to sexual maturity was backcrossed to C57BL/6J females, and subsequent generations were either intercrossed to derive homozygotes, or backcrossed to C57BL/6J mice. The microinjections, embryo transfers and DNA analyses were performed essentially as described else-

uninterrupted colinear copy of the genome, as is encountered in its normal circular configuration; second, to examine the possibility that BPV-1 could excise and replicate as an extrachromosomal element. Experiments with integrated simian virus 40 (SV40) genomes have demonstrated that partial tandem duplications facilitate precise excision by homologous recombination in conditions permissive for SV40 replication³⁻⁵. A previous study showed that when circular BPV-1 DNA was injected into mouse embryos, the transgenic mice which arose carried only integrated forms (F. Costantini, personal communication), suggesting that early mouse embryos are nonpermissive for BPV-1 plasmid replication. Thus in the present study we intended to create transgenic mice carrying integrated BPV-1 DNA in the germ line, but with a topology that might allow excision and extrachromosomal replication in somatic tissues.

Two transgenic mice arose from embryos injected with the linearized pBPV1.69 plasmid. One mouse (116) was born with limb deformities and died ~36 h after birth, and will not be discussed further. The second mouse (120) carried about five copies of the BPV1.69 plasmid, integrated in a head-to-tail tandem array. This mouse developed normally, was fertile, and trasmitted the acquired DNA as a single insertion in a mendelian fashion. Homozygotes were derived from intercross mating of siblings. No abnormalities were observed in either heterozygotes or homozygotes during the early breeding analysis.

Development of cutaneous tumours

Transgenic mice harbouring the pBPV1.69 insertion are phenotypically normal during development and early adult life. However, skin tumours begin to appear as the mice grow older. Tumours are first apparent at about 8 months of age, arise in multiple locations on the body, and eventually develop in almost every transgenic mouse in this lineage. In addition to obvious protuberant growths, large areas of the skin become abnormal, with thickening, hardening, and marked hair loss. Small wartlike protrusions are often scattered throughout areas of the abnormal skin. Tumours are most frequent in the face and head area, and on the ends of the tails of heterozygous mice, which were clipped at 3 weeks of age for DNA analysis. The tumours are initially benign, but can become malignant and locally invasive, although they have not been found to metastasize to other tissues. No examples of primary tumours arising in internal organs have been observed. Occasionally, mice become severely affected, with most of the skin becoming grossly abnormal, and multiple protuberant tumours developing on the face, neck, mouth, body and tail. There have been no examples of nontransgenic mice developing skin tumours, even following extended cohabitation with affected transgenic mice, which suggests that infectious BPV-1 virus is not being produced. This conclusion is supported by immunohistochemical analyses of affected tissues using antisera that recognize the BPV-1 capsid proteins, which have failed to detect these virion components (P. Howley, personal communication). Representative examples of the skin tumours which arise in these transgenic mice are shown in ref. 20.

Tumour pathology

Various protuberant tumours and abnormal skin were analysed after formalin fixation, standard tissue sectioning, and histochemical staining with haematoxylin and eosin: four examples are shown in Fig. 2, together with normal skin. In all cases, the affected tissues contained proliferating dermal fibroblasts, in rather disorganized sworls of densely packed cells. The obvious proliferation and disorganization of the dermal layer is characteristic of all tumours examined, and is almost always the major component of affected tissues. This characteristic is similar to that observed in dermatofibromas and fibromatoses which arise in humans⁶.

There are two different histopathologies observed in the epidermis of the affected tissues. Abnormal skin shows a grossly thickened dermal layer and an atrophic epidermis, with significant loss and disorganization of hair follicles and glands. The epidermis is only a few cells thick. One can speculate that the thickened and disorganized dermis (or the transformed state of the dermal fibroblasts) may somehow be impaired in its ability to provide the proper stratum or the required nutrients and growth factors for normal epidermal cell growth. Abnormal skin

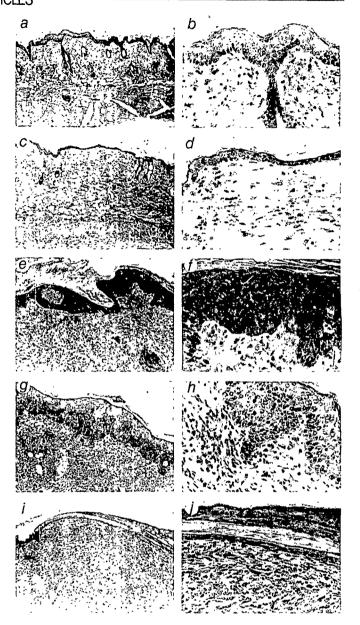

Fig. 2 Histological analysis of affected cutaneous tissue. In each case the tissue is shown at two magnifications, ×30 (left) and ×120 (right). a, b, Normal skin, with hair follicles and glands embedded in the dermis, and an epidermal layer of average size for body skin. c, d, Abnormal skin, showing hyperplasia of the dermal fibroblasts and thinning of the overlying epidermis, with loss of hair follicles and glands. e, f, Tumour at the tip of a tail, showing a disorganized and enlarged mass of dermal fibroblasts, and a hyperplastic epidermal layer. g, h, Facial tumour, with dermal fibroblast proliferation and thickening of the overlying epidermis. i., j, An anaplastic tumour, which arose on a hingleg, with multinucleated cells that are not readily identifiable as either dermal fibroblasts or epidermal epithelial cells. Tissues were excised and fixed in 10% formalin, after which they were embedded in paraffin, and thin sections taken. The sections were stained with haematoxylin and eosin in a standard histochemical process.

also shows scattered small wart-like protrusions, which appear to be focal proliferations of melanocytes characteristic of blue nevus⁶.

The second class of abnormality seen in the epidermis is associated with protuberant tumours, where the epidermis shows considerable hyperplasia. The layer of keratinocytes appears unusually thick, and the cell types may be disorganized as well. Although the extent of epidermal hyperplasia is significant, it is less than the degree of dermal fibroblast proliferation. This

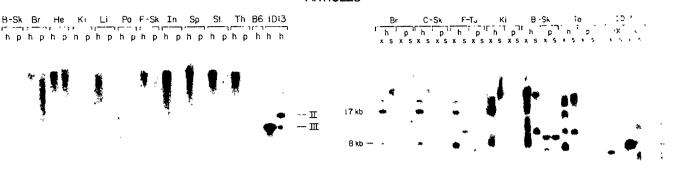

Fig. 3 BPV DNA in the tissues of a young mouse. Total DNA was isolated from a series of tissues, and fractionated into a high-M_r spooled portion (h) and a pellet fraction (p) composed of the low-M, DNA which did not spool. The DNAs were digested with SacI, which does not cut the pBPV1.69 plasmid. The DNAs were electrophoresed through a 0.5% agarose gel, transferred to nitrocellulose, and hybridized to a radiolabelled BPV plasmid. The tissues analysed are body skin (B-Sk), brain (Br), heart (He), kidney (Ki), liver (Li), pancreas (Pa), facial skin (F-Sk), small intestine (In), spleen (Sp), stomach (St) and thymus (Th). Additional tissues examined but not shown include testes, tail, body wall, lung and skeletal muscle. ID13 is a BPV-transformed C127 cell line containing ~400 copies of episomal BPV DNA. B6 is C57BL/6J DNA (from a normal mouse, which lacks BPV sequences). The positions of the relaxed circular and linear forms of extrachromosomal BPV are indicated (forms II and III, respectively). High-M, ID13 DNA (h) was digested with Xba (left- or Sac (right), to either linearize the resident BPV genome or leave it untouched.

is in contrast to naturally occurring fibropapillomas in cattle, where the dermal fibroblast and epidermal components are approximately equally represented. There are several possible explanations for this difference. One is that the penetrance of the BPV-1 oncogenes is different in two cell types, being more effective in the dermal fibroblasts than in the squamous epithelial cells; this assumes that the epithelial proliferation is a direct result of BPV-1 gene expression. A second possibility, however, is that the epidermal response is reactive to the dermal proliferation, and is not induced directly by a BVP-1-encoded function. Conversely, a third possibility is that BPV-1 gene expression in the epidermis is directing the fibroblast proliferation. The examination of these possibilities will require separate analysis of the two tissue layers.

BPV-1 genome in normal and tumour tissues

The structure and form of the BPV-1 genome has been examined in a variety of tissues in both young normal mice and in older tumour-bearing mice. In view of the possibility that BPV excises and replicates as an episome, the analysis was designed to detect free copies of the BPV genome. DNA from each tissue was separated into low- and high-relative molecular mass (M_r) fractions, which were then digested with restriction enzymes that cleave the BPV-1 genome either once (XbaI) or not at all (SacI). The SacI digestion should leave the pBPV1.69 plasmid in a fragment of very high M_r (>85 kb), composed of the head-to-tail tandem array (of about five copies) that was produced during integration after microinjection of the original embryo. In contrast, free copies of BPV-1 DNA should migrate on gels in the 8-kb range.

Figure 3 shows an example of a DNA blotting analysis of tissues in a young mouse, ~ 6 weeks old. No hybridizing bands were observed in the SacI digests of either high- or low- M_r fractions of any tissue. In comparison, the ID13 cell line, which is transformed by BPV DNA, shows 8-kb bands, demonstrating the presence of extrachromosomal DNA. This and similar analy-

Fig. 4 BPV DNA in a tumour-bearing mouse. Mouse 907 carried a facial tumour, a tail tumour growth and an area of affected skin, with substantial hair loss and dermal thickening. Tissues were collected, and DNAs extracted and analysed as described in Fig. 3 legend. The tissues analysed are brain (Br), facial tumour (F-Tu), cheek skin near the facial tumour (C-Sk), kidney (K1), abnormal body skin (B-Sk), and tail with tumour (Ta). Both spooled (h) and pellet (p) fractions were digested with either Xbal (X) or Sacl (S). Kidney DNA was applied to this analysis in a fourfold greater amount than the other tissues examined, to verify the lack of appreciable rearranged or extrachromosomal DNA in normal tissue. The positions of the three forms of extrachromosomal BPV-1 in ID13 cells are indicated by I (supercoiled), II (relaxed circular) and III (linear). Digestion with XbaI, which cuts once within the 31% fragment of BPV, should release the full-length 17-kb pBPV1.69 plasmid from the integrated concatenate, as well as linearize the 100% BPV circular form (7.9 kb) that would be released by homologous recombination across the reiteration in the plasmid. The 8-Kb band in the Xba digests of brain and cheek skin represents a rearranged copy of the input 17-kb BPV 1.69 plasmid that releases this fragment (the 100% BPV genome) from the integrated concatenate (data not shown), which was apparently produced by recombination between injected molecules during integration.

ses have shown that the BPV genome does not undergo detectable excision events in the tissues of young transgenic mice, including the skin, where tumours will arise in later life. When these same DNAs were digested with restriction enzymes that cleave the pBPV1.69 plasmid, an identical pattern was observed in every tissue; this pattern is consistent with the plasmid being present as a stable head-to-tail concatenate in high- M_r DNA (not shown).

In contrast, the analyses of mice bearing tumours revealed rearrangements in the BPV genome in all affected tissues. Figure 4 presents the analysis of one such mouse. The low M_c DNA fractions in a facial tumour, a tail tumour and abnormal skin all show free copies of BPV-1. Comparison with the unit-length BPV-1 genome maintained in cultured mouse C127 cells indicated that the episomes are predominantly full-length BPV, presumably arising from precise excision from the integrated DNA. Most of the extrachromosomal copies migrated as relaxed circular or linear DNAs (forms II and III, respectively). It is not clear whether this represents the authentic condition in the tumour cells, or rather results from the DNA isolation and Sacl digestion, which was performed to facilitate migration of high- M_r DNA in the agarose gel. Some DNAs showed additional bands which may represent the excision of the BPV/plasmid recombinant, which is also duplicated as a consequence of the head-to-tail integration observed in early embryos. The spooled high-M, fractions of the affected tissues also showed amplified BPV DNA. In skin, it seems that both free copies and in situ integrated copies contribute to the amplification. Again, normal tissues, incuding facial skin, show no amplified, rearranged or

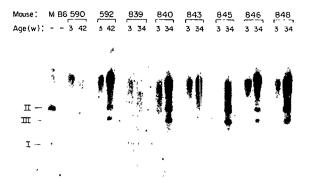

Fig. 5 Correlation between tumours and episomes. Tail DNAs were isolated from eight mice at both 3 weeks and 9-10 months old. Five of these mice (592, 840, 845, 846 and 848) had a tumour on the tip of the tail, while the other three appeared normal. The DNAs were digested with SacI and analysed as described for Figs 3, 4. The marker lane (M) contains DNA from the ID13 cell line, which contains episomal BPV: the supercoiled, relaxed circular and linear forms are indicated. B6 is C57BL/6J DNA, which does not contain BPV sequences.

free DNA. This was particularly apparent in the analysis of the kidney DNA, which was used at about a fourfold higher DNA concentration. Examination of the SacI digest revealed no extrachromosomal copies of the BPV-1 genome, and the XbaI digest was comparable to (although more intense than) brain or normal skin.

Analysis of a number of affected mice bearing protuberant tumours and abnormal skin has revealed a correspondence between the tumours and the presence of free copies of the BPV-1 genome in the DNAs of those tumours; a pertinent example is shown in Fig. 5, in which the tail DNAs of several mice are analysed. The tails were originally clipped at 3 weeks old, to assess transmission of the transgene. At approximately 10 months of age, an additional portion of the tail from each mouse was removed, and the DNAs were subjected to the blotting analysis described above. Five mice were seen to have free copies of the BPV-1 genome in their tail tissue at 10 months of age, while none had any detectable levels at 3 weeks. These five mice had tumour growth on the tips of their tails, while their siblings did not. As in the results shown in Fig. 4, again there was a correspondence between free copies of the BPV-1 genome and the presence of abnormal tissue.

Genetic aspects of tumour development

The characteristics of tumour formation suggest that these transgenic mice will be useful in the study of secondary events which participate in oncogenesis. The presence of the BPV oncogenes is apparently insufficient, in that the tumours arise after a long latency. Furthermore, tumours occur most frequently in areas prone to wounding. There is precedent for irritation and wounding as cofactors in a variety of cancers, including BPV-induced fibropapillomas in cows^{1,2}, crown gall tumours in plants⁷, and Rous sarcoma virus-induced sarcomas in chickens⁸, as well as in experimental animal models of tumour progression9-11.

Thus, the BPV-1 genome can be considered to be a genetic predisposition to the induction of fibropapillomas of the skin, one which requires additional events before oncogenesis occurs. One prospective event might be the transcriptional activation of a dormant BPV genome, as this has been observed both in studies of BPV-1 transformation of cultured cells12, and in oncogenesis induced through persistent papillomavirus infection of the Brazilian rat¹³. In addition, there is a high incidence of BPV-1-induced tumours in cows grazing on bracken fern, which is tumourigenic in laboratory animals, and which may be acting as a cofactor in this natural oncogenesis¹⁴. The ability of carcinogens15 or prospective cellular (growth) factors16 to complement the BPV oncogenes in tumour development can be assayed directly using these transgenic mice.

In a previous study (R. Palmiter and R. Brinster, personal communication), 15 lines of transgenic mice harbouring the BPV 69% transforming region were generated and maintained for 10 months. No abnormalities were observed in any of these lineages, which suggests that either the topology of the BPV1.69 plasmid or the presence of the 31% portion of the BPV genome is important for the phenotype described here. Consistent with this possibility is the observation of Sarver et al. 17 that the complete genome is more efficient at transforming C127 cells than is the 69% fragment, as well as the recent studies of Lusky and Botchan¹⁸, which demonstrated that the 31% region contains a cis-acting element that stimulates efficient BPV plasmid replication in cultured cells.

Thus, transgenic mice provide a new model in which to study the tissue specificity of BPV gene expression, the activities of the BPV oncogenes, and the genetic requirements of the BPV-1 genome in eliciting neoplasia—in particular, the implications that either the 31% region, extrachromosomal replication, or gene amplification could be important for oncogenesis. The present results also presage similar application of this approach to human papillomavirus genomes.

We thank Peter Howley for many helpful discussions, for advice and analyses on tumour pathology and for comments on the manuscript; Dan DiMaio for the gift of the pBPV1.69 plasmid and for discussions during the initiation of this project; Richard Palmiter for discussions and comments on the manuscript: Jean Roberts, Mike Ockler and Dave Green for artwork and photography; and Marilyn Goodwin for preparing the manuscript. The research was supported by a grant from Monsanto Company, as well as by funds from the National Foundation for Cancer Research and the Leukemia Society of America.

Looking for cosmic strings

Alexander Vilenkin

Physics Department, Tufts University, Medford, Massachusetts 02155, USA

Cosmic strings predicted in some grand unified theories can produce double images of distant galaxies and quasars¹⁻³, and it has been argued that some of the known double quasars may be due to strings²⁻⁴. To test this hypothesis, one can look for other characteristic effects of strings in the vicinity of double quasars, such as a discontinuous change of the microwave background temperature across the string^{3,5}, lines of double galaxies², and images of galaxies with a sharp edge4. In most of the previous work on the gravitational effects of strings it was assumed either that the string is static or that both the string and its velocity are perpendicular to the line of sight. Here I show that in more general configurations the expressions for the angular separation of double images and for the temperature discontinuity $\delta T/T$ across the string are modified by trigonometric and relativistic factors. More importantly, the line connecting the double images is not, in general, perpendicular to the apparent direction of the string (contrary to what one would naively expect). Although the analysis presented here is rather elementary, the results may nevertheless be useful for interpreting the observations.

We first consider the situation in the rest frame of the string. The metric of a straight static string is a conical space^{1,3}. It is locally flat, but has an angle deficit

$$\delta = 8\pi G\mu \tag{1}$$

where G is the gravitational constant and μ is the mass per unit length of string. This space can be obtained from a euclidean space by cutting out a wedge of angular width δ and identifying the exposed surfaces. The existence of strings can be consistent with the isotropy of the cosmic microwave background only if $G\mu < 10^{-5}$, and we shall assume this to be the case. The angular separation of double images due to a string is given by^{2,3}

$$\delta\varphi_0 = l(d+l)^{-1}\delta\sin\theta\tag{2}$$

where d and l are the normal distances from the observer and from the quasar to the string and θ is the angle between the string and the line of sight.

Strings are expected to move at relativistic speeds, the mean square velocity (in units of c, the speed of light) being $\langle v^2 \rangle = 0.5$ (with respect to local co-moving frames). Because only transverse motion of strings is observable, we shall assume that \mathbf{v} is perpendicular to the direction of the string. To find the angular separation between the images in the observer's frame, let \mathbf{k} and \mathbf{k}' be the four-dimensional wave vectors of the light waves (with frequencies ω and ω') corresponding to the two images, and consider the invariant $\mathbf{k} \cdot \mathbf{k}' = \omega \omega' [1 - \cos{(\delta \varphi)}] \approx 0.5 \ \omega \omega' (\delta \varphi)^2$.

consider the invariant $\mathbf{k} \cdot \mathbf{k}' = \omega \omega' [1 - \cos{(\delta \varphi)}] \simeq 0.5 \omega \omega' (\delta \varphi)^2$. In the rest frame of the string, S_0 , the two frequencies are equal: $\omega = \omega' = \omega_0$. In the observer's frame, S_0 , ω and ω' are slightly different because of the difference in the directions of \mathbf{k} and \mathbf{k}' . However, the difference is of the order of $\delta \varphi$ and can be neglected to the lowest order in $G\mu$; thus, $\omega \delta \varphi = \omega_0 \delta \varphi_0$. The frequencies ω and ω_0 are related by $\omega = \gamma (1 - \mathbf{n} \cdot \mathbf{v}) \omega_0$, where \mathbf{n} is the direction from the observer to the quasar, \mathbf{v} is the velocity of the string (that is, the velocity of S_0 relative to S) and $\gamma = (1 - v^2)^{-1/2}$. Hence,

$$\delta \varphi = \gamma^{-1} (1 - \mathbf{n} \cdot \mathbf{v})^{-1} \delta \varphi_0 \tag{3}$$

Depending on the relative directions of **v** and **n**, the angular separation has a value in the range $\kappa^{1/2}\delta\varphi_0 < \delta\varphi < \kappa^{-1/2}\delta\varphi_0$, where $\kappa = (1-v)/(1+v)$. Note that long strings are expected

to be at large redshifts, and hence to have a tendency to move away from us. (Here and below, I ignore the complications introduced by space-time curvature.)

The temperature discontinuity across the string arises because the relative velocity of two objects in a conical space is double-valued⁵: the answer depends on which way one parallel-transports the velocities around the string. In the rest frame of the string, S_0 , the observer moves past the string with velocity $-\mathbf{v}$. If the observer is at rest with respect to the sources of radiation on one side of the string, then the velocity of the sources on the other side of the string is $-\mathbf{v}+\mathbf{u}_0$, where $\mathbf{u}_0=8\pi G\mu$ $\mathbf{v}\times\mathbf{s}$ and \mathbf{s} is a unit vector along the string. The corresponding velocity difference in the observer's frame S is $\mathbf{u}=\gamma\mathbf{u}_0$. (Here I have expanded \mathbf{u} to the lowest order in $G\mu$ and used the fact that $\mathbf{u}_0\cdot\mathbf{v}=0$.) The temperature discontinuity can be found from the Doppler formula, $\delta T/T=\mathbf{u}\cdot\mathbf{n}$, where \mathbf{n} is a unit vector along the line of sight; thus,

$$\delta T/T = 8\pi G\mu\gamma \mathbf{n} \cdot (\mathbf{v} \times \mathbf{s}) \tag{4}$$

This expression has been derived in a different way by Vachaspati⁶.

If a segment of rapidly moving string is not perpendicular to the line of sight, then the observer sees more distant parts of the string with a retardation, and the apparent direction of the string differs from its actual direction. For simplicity, I shall consider only the case when the velocity of the string is perpendicular to the line of sight. Consider a coordinate system with y-axis along the line of sight and z-axis along the velocity of the string, so that the orientation of the string is parallel to the x-y plane. The observer sees a projection of the string on the x-z plane. Two points of the string with x-coordinate difference Δx are seen with a relative time delay $\Delta t = \Delta x \cot \theta$; hence, the observed difference in z-coordinates is $\Delta z = v\Delta t = (v \cot \theta)\Delta x$. The angle χ between the apparent and the actual direction of the string can be found from

$$\tan \chi = v \cot \theta \tag{5}$$

If there is a double quasar due to this string, then the line connecting the two images is along the z-axis and is not, in general, perpendicular to the apparent direction of the string (which can be observed, for example, by detecting the microwave temperature discontinuity).

Equation (5) applies to a relatively short segment of string subtending a small angle from the position of the observer. If an infinite straight string moves past the observer, he sees its distant parts with a retardation, so that the string appears to him to be curved. In the rest frame of the string, S_0 , light rays received at the origin at time $t_0 = 0$ were emitted from the string at space-time points

$$x_0^{\mu} = \{-(a^2 + \sigma^2)^{1/2}, \mathbf{a} + \sigma \mathbf{s}\}$$
 (6)

Here, a is the normal vector from the origin to the string, $s \perp a$ is the unit vector along the string and σ is a parameter on the string (equal to the length along the string measured from the end of vector a). We introduce a coordinate system with x-axis parallel to the string and z-axis along the velocity of the string in the observer's frame, S, and assume that the origins of S_0 and S momentarily coincide at $t = t_0 = 0$. The coordinates of the emission events in frame S are found from equation (6) by a Lorentz transformation; the spatial components are given by $x = \sigma$, $y = a_y$, $z = \gamma [a_z - v(a^2 + \sigma^2)^{1/2}]$, where $a^2 = a_y^2 + a_z^2$. To represent the apparent shape of the string, this three-dimensional curve must be projected onto a plane. A central projection from the origin to the plane $y = a_y$ gives

$$z = \gamma v [a - (a^2 + x^2)^{1/2}] \tag{7}$$

where I have set $\alpha_z = va$, so that z(x=0) = 0. Hence, a rapidly

moving infinite straight string appears to have the shape of a

Cooling flows in ellipticals and the nature of radio galaxies

Mitchell C. Begelman

Joint Institute for Laboratory Astrophysics, University of Colorado and National Bureau of Standards, Boulder, Colorado 80309-0440, USA

One of the great puzzles in the study of active galaxies is the relationship between the properties of the nucleus and the largescale morphology of the host galaxy. Galaxies which produce extended radio sources but little optical, ultraviolet or X-ray emission are invariably giant ellipticals or cD galaxies, whereas spirals tend to host 'optically active' nuclei, such as Seyferts¹ and at least some quasars^{2,3}. Rees and co-workers⁴⁻⁶ have interpreted this difference in radiative efficiency as a manifestation of the accretion flow close to the central black hole. But why should the mode of accretion at several Schwarzschild radii depend on the large-scale morphology of the host galaxy? I argue here that the connection arises from the manner in which interstellar gas is fed into the nucleus.

According to the scheme proposed by Rees et al.4, radio galaxies possess tenuous 'ion tori' which produce little radiation at optical, ultraviolet and X-ray wavelengths, whereas quasars and Seyfert galaxies possess optically thick accretion flows which radiate copiously. The mode of accretion depends on the ratio \dot{m} of the accretion rate to the 'critical' accretion rate $L_{\rm F}/c^2$, where $L_{\rm E}$ is the Eddington limit and c is the speed of light. Given a viscosity parameter α (ref. 7), the flow is always a gas-pressure-supported 'ion torus' for $\dot{m} < 10^{-7} \alpha^2$ and is either a standard thin accretion disk ($\dot{m} < 10$) or a 'radiation torus' $(\dot{m} > 10)$ for $\dot{m} > 50\alpha^2$. For intermediate values of \dot{m} , however, the flow may assume one of two possible states: a thin disk or an ion torus. The flow pattern adopted probably depends on the manner in which gas is fed into the nucleus. In a spiral galaxy, the bulk of the interstellar medium resides in a disk, and it is plausible that a radiatively efficient flow pattern persists all the way to the black hole. Thus it seems natural that spiral galaxies should produce optically active galactic nuclei.

The situation is quite different for elliptical galaxies, which are permeated by a hot interstellar medium at a temperature close to the virial temperature of the galaxy⁸⁻¹⁰. X-ray measurements of this gas suggest that it is slowly cooling and settling into the potential well of the galaxy at a rate ranging from $\sim 1~M_{\odot}~\rm yr^{-1}$ for isolated ellipticals^{8,11,12} to $\sim 1,000~M_{\odot}~\rm yr^{-1}$ for the outer regions of central ellipticals in rich clusters^{13,14}. (M_{\odot} is the mass of the Sun.) Cooling flows are strongly thermally unstable to the formation of cool clumps, and it has been suggested that the formation of low-mass stars continuously removes mass from these flows at all radii15,16. Indeed, there are observational indications that the mass flux declines steadily towards the centre^{13,17}. In the limiting case, thermal instabilities could remove enough material at every radius so that the residual inflow of hot gas would remain subsonic, cooling on a timescale

comparable to or longer than the free-fall time in the galactic potential⁸. Matters are complicated somewhat if the flow passes through a sonic point^{18,19}. In principle, a cold supersonic flow could continue into the nucleus with the mass flux conserved; however, it is more likely that inhomogeneities in the flow, leading to shocks, would reheat some of the gas to a temperature comparable to the virial temperature, while most of the gas condenses into cold blobs which follow ballistic trajectories. Even a small amount of angular momentum will deflect these blobs from radial orbits; the high pressure in the ambient hot gas will compress them, reducing their collision cross-sections and making it likely that they, too, will form stars before they coalesce into an accretion disk at the galactic centre. As in the subsonic case, the characteristic cooling time of the hot gas will be comparable to or longer than the free-fall time.

Suppose there is a black hole at the centre of the galaxy, of mass $M_h = 10^9 \,\mathrm{M}_\odot \,M_\odot$ (that is, of mass M_\odot in units of $10^9 \,M_\odot$). The gravitational potential of the black hole begins to dominate the dynamics of the hot gas at a radius

$$R_{\rm h} \simeq GM_{\rm h} m_{\rm o}/kT \simeq 50 \ M_{\rm g} T_{\rm 7}^{-1} \ {\rm pc}$$
 (1)

where T_7 is the temperature of the gas in units of 10^7 K. If the cooling time of the hot gas at $R \ge R_h$ is comparable to or longer than the local free-fall time, then the density of hot gas at R_h , $n(R_h)$, satisfies

$$n(R_{\rm h}) \le 10 \ M_9^{-1} T_7^{3.1} \ {\rm cm}^{-3}$$
 (2)

where I have used a power-law approximation²⁰ for the cooling rate at $10^5 \text{ K} < T < 3 \times 10^7 \text{ K}$. The Bondi theory of spherical accretion21 then gives an upper limit to the black hole accretion rate (first pointed out by Nulsen et al.8):

$$\dot{M} \lesssim 2 M_9 T_7^{1.6} M_{\odot} \text{ yr}^{-1}$$
 (3a)

$$\dot{m} \leqslant T_7^{1.6} \tag{3b}$$

Equations (3a) and (3b) are valid whether or not additional cooling occurs at $R < R_h$.

In fact, the hot inflow is likely to become angular-momentumdominated before it reaches R_h . If the timescale for angular momentum transport reduces the inflow speed by a factor α , then the upper limits given in equations (3a) and (3b) will be reduced by a factor α^2 . As the cooling time is already of the order of the inflow time at $R \ge R_h$ (the definition of a cooling flow), one can show that the flow at $R \leq R_h$ will never be able to cool by line-cooling or bremsstrahlung, provided α does not decrease too rapidly with decreasing R (ref. 4). Under the assumptions made by Rees et al.⁴, the inner parts of the flow will form an ion torus if $\dot{m} < 50 \ \alpha_{\rm in}^2$, where $\alpha_{\rm in}$ is the value of α in the inner parts of the flow. This condition is satisfied if

$$T_7^{1.6} < 50(\alpha_{\rm in}/\alpha)^2$$
 (4)

Again, we conjecture that the highly compressed cold clumps will form stars before they are able to coalesce to form a nuclear disk; hence, only the hot gas participates in the angularmomentum-dominated accretion flow.

Equation (4) is probably satisfied in most elliptical galaxies; therefore, most active elliptical galaxies should possess radiatively inefficient ion tori, consistent with observations. As suggested by Sparke and Shu²², the development of large-scale collimated radio jets may be fostered by the presence of a hot interstellar medium in ellipticals, and suppressed by its absence in spirals. I therefore suggest that the large-scale morphology of the galaxy governs both the large-scale radio structure and the small-scale structure of the active nucleus.

Note that the upper limit on \dot{m} (Equation (3b)) depends only on the temperature of the cooling flow in the galactic potential and is independent of the mass of the hole. For a variety of plausible galactic potentials, $T^{1/2}$ would scale with the central stellar velocity dispersion (excluding the cusp surrounding the black hole), which in turn is correlated with the luminosity of the galaxy according to the Faber-Jackson relation²³. This chain of argument leads to a predicted correlation between \dot{m} and the luminosity of the host galaxy. In particular, equation (4) may be violated for the most luminous ellipticals. The inflow would become a radiatively efficient thin disk or radiation torus, and the resulting objects would be classified as luminous quasars. Besides residing in elliptical galaxies, these 'elliptical' quasars might be expected to differ from 'spiral' quasars in their radio properties. If we accept the view of Sparke and Shu²², the distant guasars which produce highly collimated luminous jets extending to several hundred kiloparsecs—such as 4C32.69 (refs 24, 25)—should be examples of this second class of quasars. There are additional indications from optical studies that radio-loud quasars tend to be associated with elliptical galaxies^{26,27} although these studies are far from definitive.

Certain classes of active ellipticals, notably BL Lac objects and N galaxies, might be considered optically active, yet are not excessively luminous. It is not clear whether these can be easily accommodated in the scheme outlined above. For BL Lac objects, a case can be made that we are viewing an ion torus pole-on. Alternatively, catastrophic Compton cooling resulting from pair production can sometimes collapse the inner regions of an ion torus, converting it to a radiatively efficient thin disk³⁰. Finally, emission lines from photoionized gas have been detected in the nuclei of many 'normal' radio galaxies, indicating that some ultraviolet or X-ray continuum is produced in these objects as well. This need not imply a high radiative efficiency of the central engine, as ion tori are expected to produce a certain amount of hard radiation. In fact, a modest radiative efficiency in X-rays may reduce the accretion rate below the value estimated above, by heating the inflowing gas^{28,29}

I thank Craig Sarazin, Marek Sikora and Janet Drew for helpful criticism. This research was funded in part by NSF grant AST83-51997 (Presidential Young Investigator Award), by NASA Astrophysical Theory Center grant NAGW-766, and by grants from Ball Aerospace Systems Division, Rockwell International Corporation and the Exxon Education Foundation.

Secular change in solar activity derived from ancient varves and the sunspot index

C. P. Sonett* & T. J. Trebisky†

* Department of Planetary Sciences and Lunar and Planetary Laboratory, and † Steward Observatory, University of Arizona, Tucson, Arizona 85721, USA

The Hale solar period, $\tau_{H(1)} \approx 22 \text{ yr}$, and its second harmonic, $\tau_{H(2)} \simeq 11$ yr, which characterize the sunspot index and are thus hydromagnetic, are imprinted in certain varved rocks of Archaean1to late Precambrian2 age, but the varves record climate and thus are sensitive to solar insolation^{2,3}. We report here apparent collective behaviour of the two kinds of data. The 22yr/11-yr amplitude spectral density (ASD) ratio, β_i (i = 1) of the sunspot index (which is a measure of solar-cycle asymmetry), plotted together with β_i s from three ancient varve thickness sequences against the age for each β_i , results in a remarkably close fit to a decreasing exponential with time constant $\tau \approx 2$ Gyr. These varves and the sunspot index appear to link solar luminosity and the solar field, implying that a common forcing mechanism affects luminosity and the dynamo periods through the common decay time, τ .

Varve data comprise a sequence of thickness values of sediments or chemical layers indexed by integers hypothesized to correspond to solar years. The observation of ~11- and ~22-'year' periodicities lends strength to the hypothesis. (The lack of exact correspondence for all the data of this report is discussed below.) Data of the quality of the Elatina sequence² have been reported nowhere else; the Hamersely group has much more material but has not been fully surveyed for data pertaining to the solar problem. In view of the paucity and special qualities of these data, it cannot be guaranteed that further 'finds' will not alter the interpretation given here; nevertheless, we think it

important to report these very tentative findings for their potential role in solar physics. The four sources of data used to determine the β_i s and τ were: (1) the Weeli Wooli (Hamersely) banded iron formations¹ (2.5 Gyr BP); (2) the Wolongorang (McArthur basin) dolomitic varves⁴ (1.75 Gyr BP); (3) the Elatina sedimentary varves² (0.67 Gyr BP); and (4) the presentepoch sunspot index, representing a significant spread in ages. Errors in ages are uncertain, but are in all cases much smaller than the confidence spreads shown in Fig. 2. For Weeli Wooli (thin-section photographic transparency) and Wolongorang (thin section) the procedure for determining varve thicknesses was that used previously⁵ for the light bands in the Elatina sequence, namely, measurement of thickness using a long stagemicrometer with an optical shaft-encoder fed to a small computer for recording.

For computing spectra we generally used the preferred digital Fourier transform (DFT), supported on occasion by a maximum entropy method (MEM). The sunspot index spectrum (computed by DFT) is shown in Fig. 1a, b. In a the plot is linear-linear for clarity, whereas b is log-linear (and filtered) to enhance the small response near 22 yr. We used the prior knowledge of these periods to aid identification of the region in frequency space (unsmoothed for maximum resolution) where the Hale line and its second harmonic were expected. For Elatina those periods were previously determined to be ~12 and 24 yr (ref. 5), rather than the modern 11 and 22 yr from the sunspot index. For the more ancient Wolongorang varves the shift was greater, corresponding to periods of ~14.8 and 28.8 yr, respectively. (A correspondingly greater shift for Weeli Wooli is not apparent, but its does have a 23.3-yr period¹.) The 'solar' lines were further certified as the strongest present, and also as satisfying closely a 2:1 ratio of periods. For the final ASD estimates used to calculate β_i s, a simple 5-point boxcar averaging filter was used to smooth the spectra.

As the DFT estimates follow a χ^2 distribution, the β_1 s (being a ratio) follow an F distribution. Our next point, regarding degrees of freedom, is crucial to the estimation of the confidence

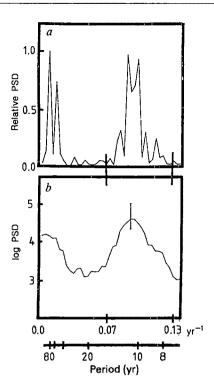

Fig. 1 Digital Fourier power spectral density (PSD) of the Wolf yearly averaged sunspot index. a, Unsmoothed 2-DOF relative amplitude, plotted against frequency (upper x-axis) and period; linear-linear plot. Plot b (log-linear) emphasizes minor 22-yr power by using a logarithmic ordinate. Error bar, 90% χ^2 confidence limit. This present-epoch case shows $\beta_1 \approx 0.1$.

intervals. Assuming that all four β_i s are independent, the filtering yields 10 degrees of freedom (DOF) per DFT datum and narrows the χ^2 confidence range considerably. But these data must be and are obviously correlated. The optimistic limit would be \sim 40-80 DOF per datum. For the 80% confidence level of the final F distributions, the sensitivity of the confidence range to changes in the number of DOF near 40 is small⁶, and the 80% ranges in Fig. 2 are reasonable. (In the indexing of β_i , i increases with age.)

Fig. 2 shows the least-squares fit of the β_i s to an exponential function. The fit is computed assuming equal relative weighting, as all confidence levels are equal. Although significant deficiencies exist in the Wolongorang data, it is remarkable that β_3 lies almost exactly on the least-squares line. (As it is only the ratios of ASDs which are required, common-mode sources of error, which are independent of frequency, are unimportant.) The secular trend in the β_i s and the time constant τ are most readily explained as being due to a relict magnetic field⁷—but only if it is accepted that somehow the varves are proxy field detectors and therefore equivalent to the sunspot index in detecting the hydromagnetic asymmetry found in that index.

The decay of an axially symmetric eddy current for an isotropic sphere of radius R, with homogeneous conductivity σ , has a time constant τ_s , given by

$$\tau_s = \mu_0 \sigma R^2 / \pi^2 s^2 \text{ (MKS)} \tag{1}$$

where $\mu_0 = 4\pi \times 10^{-7}$ H m⁻¹ is the permeability of free space and s is the multipole order. It is reasonable to take s=1, for a relict field must be of odd order to explain the sunspot sequence asymmetry. As τ_s varies inversely with s^2 , it seems unlikely that any higher-order multipole from the time of the Sun's formation is still significant. Cowling⁸ computed the value $\tau_s=5$ Gyr for a relict solar field using a homogeneous sphere of radius equal to half the solar radius and $\sigma=10^7$ S m⁻¹; the value of τ_s found here is in reasonable agreement. Estimation of τ_s is made more complex by the strong variation of conductivity with temperature

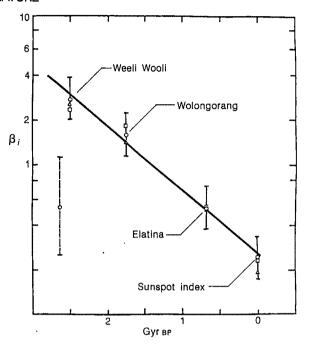

Fig. 2 Least-squares fit of the four values of β_i . The vertical errors are estimated from the F distribution function with 40 DOF. (As noted in the text, in this range of large DOF, F varies little.) Horizontal errors from geochronology and stratigraphy are unimportant compared with those of the β_i s and are not shown. \bigcirc , 5-datum filter; \square , 3-datum filter; \triangle , unfiltered. Solid line, semi-log fit $y = a \exp(-bt)$ with $b = 2 \text{ Gyr}^{-1}$; dashed line, confidence estimate for a single value of β with 10 DOF; that is, the worst possible case (independent or uncorrelated β_s).

(and therefore radius), and because the circulating currents are likely to occur where the conductivity gradient is largest; Cowling's conductivity varies with solar radius by nearly three orders of magnitude. Considering the paucity of data, we are not prepared to claim that a relict magnetic field must be responsible for the apparent joint 'bolometric'-hydromagnetic behaviour summarized in Fig. 2, but this is the best interpretation of the data available so far.

Although the Wolongorang data is of marginal quality, it covers a crucial time period (~1.75 Gyr BP); the short (54 data) sequence had to be subjectively selected from a longer sequence displaying distortion similar to the inclusions seen in the Weeli Wooli formation, possibly due to diagenesis. The dominant spectral peak positions for the Wolongorang varves may be artefacts of the short and distorted record, but the lines chosen are the strongest ones of the DFT and adhere closely to the 2:1 rule regarding harmonic periods. As both the Elatina and Wolongorang varves exhibit 'solar' lines displaced from the modern values, the periods increasing with age, perhaps something more may be indicated, such as a secular decrease in the convective zone thickness with age, in turn affecting the dynamo period. However, this must be regarded as conjecture until more data become available.

The major issue raised by these data is why luminosity and magnetic activity should appear to be linked, as shown in Fig. 2. The magnetic field is favoured as the basic variable only because it is the only solar parameter, except the core composition itself, that is capable of entering into a secular decay measured in Gyr. A relict field can explain the asymmetry in the sunspot sequence (or equivalently why both 22- and 11-yr periods are present), provided that the sunspot index varies with the energy in the field, that is, with B^2 . The sunspot index y(t) can be predicted by the equation

$$y(t) \simeq [\delta + \beta \cos(\omega_c t)]^2$$

= $\delta^2 (1 + \varepsilon^2 / 2) + 2\varepsilon^2 \cos(\omega_c t) + (\varepsilon^2 / 2) \cos(2\omega_c t)$ (2)

where β is the Hale-period amplitude in the sunspot index sequence, ω_c the Hale frequency, δ an offset (relict), $\varepsilon = \beta/\delta$, and the ratio of 22- to 11-yr amplitudes is $4\delta/\varepsilon$. A simpler model assumes that v(t) depends only on the magnitude of solar activity, but to explain the asymmetry requires complications beyond the scope of the present work. We cannot distinguish between a steady or secular value of δ and one which oscillates so slowly as to appear constant over the 282 yr of unbroken sunspot index record, but the latter option has difficulty in explaining the very long characteristic time, τ , shown in Fig. 2.

The sunspot asymmetry alone suggests a relatively small value of steady magnetic field strength; the inferred time constant, if attributed to magnetism, is consistent with its being the vestige of a much stronger pre-main-sequence field. Although a field of the magnitude inferred for the present epoch is dynamically unimportant now (except for the angular momentum problem¹⁰), it could explain the appearance of both the 11- and 22-yr activity periods. It also supports the general principle of an early Solar System magnetic field, either a compressed nebular remnant, a consequent of a nebular dynamo, or some combination of these¹¹. Although the results reported here suggest a role for magnetic fields in association with the protosolar condensation, a relict field offers no obvious explanation for the apparently coupled behaviour of insolation and solar activity. Furthermore, even a modest present-epoch relict field is inconsistent with the observed increase of angular velocity with depth

in the deep solar interior^{12,13}, a problem which is much more severe for the ancient Sun. Finally, the discussion here of periodicities bypasses consideration of statistically oriented (for example, strange attractor) models of solar activity, which may require consideration, although there appear to be difficulties with data quality14.

We are indebted to M. J. Jackson for the loan of a Wolongorang core thin section, to A. F. Trendal and R. Davy for their illumination of the systematics of the Weeli Wooli banded iron formation and the donation of a specimen, and to G. E. Williams for discussions of the subject of varves and for the loan of a Weeli Wooli thin section. This work was supported by the research program of the Atmospheric Sciences Division of NSF.

Diurnal cycle of tropospheric OH

T. M. Hard, C. Y. Chan, A. A. Mehrabzadeh, W. H. Pan & R. J. O'Brien

Chemistry Department and Environmental Sciences Doctoral Program, Portland State University, Portland, Oregon 97207, USA

The hydroxyl free radical, OH, is sunlight's prime agent in maintaining the trace-gas composition of the Earth's troposphere, and at the same time serves as the catalyst responsible for many of the symptoms of urban and regional air pollution. We have used low-pressure fluorescence to measure the ambient concentration of this radical during two continuous 36-hour periods in early summer and late autumn, 1985. The summer and autumn maxima were 3×10^6 and 4×10^5 molecules cm⁻³ (10^{-13} and 2×10^{-14} relative to air), respectively. The observed concentrations lie within the rather large latitude of current estimates based on trace-gas lifetimes or atmospheric photochemical models.

In the global troposphere, reactions with OH are part of a cleansing process, countering natural and man-made inputs. In this contest, interest has centred on methane, the most abundant atmospheric hydrocarbon. Recent observations¹⁻³ imply a persistent imbalance between methane's sources and its removal by OH. Where anthropogenic emissions of other trace gases are concentrated, some of the intermediate products of the OHcatalysed cleansing process are known as urban smog, and some of the final products are known as acid rain. Moreover, because OH controls the atmospheric lifetimes and distributions of most trace gases, secular changes in the tropospheric OH concentration will modify the global thermal radiation budget and the total ozone column.

Direct local observation of tropospheric OH has been notoriously difficult, due to its high reactivity and low concentration. OH measurements have been sporadic, and reported concentrations have varied over a large range, with large measurement uncertainties⁴. Laser-excited fluorescence^{5,6} measurements have suffered from ambient light background, fluorescence of other species, photolytic production of OH by the laser, and

calibration uncertainties. The obstacles to fluorescence determination of OH are significantly lowered by expansion of the air sample to low pressure, in a procedure we have named FAGE (fluorescence assay with gas expansion)⁷. The chief obstacles to previous determinations of OH have been the solar background at the fluorescence wavelength, and production of OH by the laser itself through photolysis of ambient ozone in the sequence:

$$O_3 + h\nu \to O(^1D) + O_2$$
 (1)

$$O(^{1}D) + H_{2}O \rightarrow 2 OH$$
 (2)

Here $h\nu$ indicates the exciting laser radiation (which then detects the spurious OH during the same pulse) and O(¹D) is the first excited state of the oxygen atom. In FAGE, we draw ambient air through an orifice and down a tube to the excitation and detection zone at a pressure of ~5 torr. This pressure drop strongly discriminates against step (2) above and against Rayleigh and Mie scattering, the latter particularly a problem in polluted air. The contained environment excludes ambient light. The roughly 100-fold drop in OH concentration associated with the expansion is compensated by an approximately equal increase in the fluorescence yield due to reduced fluorescence quenching at the lower pressure. In addition, reduced quenching results in a longer fluorescence lifetime so that most of the fluorescence waveform is temporally separated from the instantaneously scattered pulse. Finally, the low-pressure transit down the tube to the detection zone allows reagents added at the inlet to react selectively with OH, so that the background signal may be accurately and continuously determined (chemical modulation of the signal).

The FAGE method and instrument have been described elsewhere⁷. To make the measurements reported here, we have substantially improved the sensitivity to ambient OH with a new YAG/dye laser (repetition rate increased from 6 to 30 Hz and 282-nm pulse energy increased from 0.1 to 1 mJ); by replacing the monochromators at f/4 (where f is the focal length) by 3-nm (FWHM) multi-layer dielectric filters at f/1.5; and by the use of two parallel air-sampling and fluorescence-detection channels, sharing one 0.5-m White cell. A flow of isobutane sufficient to remove 95% of the OH is injected alternately into the interior of each probe, giving a modulation cycle of 90 s duration. Thus, the signal and the background are measured simultaneously by the pair of probes. Figure 1 is a diagram of the FAGE sampling cell. This sampler was placed 2 m above the roof of our four-story building; the vacuum pump, laser and signal-processing electronics were in the laboratory immediately below.

Our initial goal in developing this technique has been to determine the diurnal concentration profile of OH in tropospheric air, to verify the behaviour projected by atmospheric models. Figure 2 shows the OH concentration observed during a 36-h experiment in Portland, Oregon, on 17-19 June 1985. The darker points are a 1-h moving average; the lighter points are at ±2 standard deviations, as dictated by the photon counting statistics of the total signal and background. (This uncertainty is twice the square root of the sum of the photon counts from the two probes.) Averaging of the raw data is necessary to reduce noise—a 1-h average results in negligible distortion of the true curve.

'The concentration scale in Fig. 2a is determined by the FAGE instrument's OH response, which was measured before and after the experiment, over the range of (intended) measurements. Full calibration of the response (Fig. 3) was carried out by surrounding the sampling probes with an ultraviolet-transparent teflonfilm bag, into which flowed a continuous air stream containing trace levels of nitric oxide (NO) and hydrocarbon (mesitylene). The bag was irradiated continuously with ultraviolet fluorescent lamps, and the hydrocarbon, NO and ozone concentrations were measured at the bag inlet and in the interior. A fan ensured that the bag operated as a well-mixed reactor with a residence time t_{res} , given by the ratio of its volume V to the total air flow rate F. The input flow was greater than that required by the NO. ozone, hydrocarbon and FAGE measurements, and excess air escaped from the bag through an outlet to the atmosphere. Once steady state has been achieved (as evidenced by unchanging concentrations), mass balance of the hydrocarbon (HC, which reacts only with OH) requires that $F[HC]_0 - k_{OH+HC}[OH] \times$ [HC]V - F[HC] = 0, where the subscript zero denotes the inlet concentration. Substituting for the bag residence time gives

$$[OH] = \frac{1}{k_{OH+HC}t_{res}} \left(\frac{[HC]_0}{[HC]} - 1 \right)$$
 (3)

For mesitylene, $k_{\rm OH^+HC}=6\times10^{-11}$ molecule⁻¹ cm³ s⁻¹ (ref. 8). The residence time was obtained from the response of [NO] or [HC] to a step change in [NO]₀ or [HC]₀ in the dark. The inlet-to-outlet ratio [HC]₀/[HC] was determined by gas chromatography with a variety of lamp intensities and inflow rates of NO, thereby producing a wide range of OH concentrations. This also produced values of the ratio [NO]/[O₃] respresentative of the entire span of NO photo-oxidation in 'classical' photochemical air pollution⁹⁻¹¹. This calibrator represents an eulerian approach to each point in the NO photo-oxidation sequence, in contrast to our previous calibration⁷, which employed a lagrangian sweep through the whole sequence. Both give similar results, and in our previous calibration the decay of two separate hydrocarbon species was monitored, each one giving the same value for the OH concentration.

The rather large scatter of the points in Fig. 3 is due in part to the fact that they were obtained over the course of about a week, with variations in laser energy and alignment with roof-top optics un-normalized. The central line in Fig. 3 is the linear-least-squares fit of the measured (hydrocarbon decay) OH concentrations to the FAGE signal.

The precision of the net OH signals in Fig. 2a is equivalent to an error in OH concentration of $\pm 4 \times 10^5$ cm⁻³ at 2 standard deviations (95% confidence, 1-h average). The accuracy of the concentrations in Fig. 2a is limited by the uncertainties in slope and intercept of the calibration in Fig. 3. The intercept uncer-

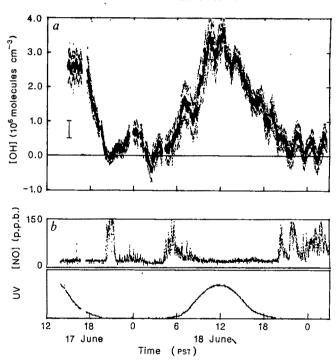

Fig. 2 a, Ambient OH concentration during 17-19 June 1985. The darker points represent a 1-h moving average; the lighter points are at ± 2 standard deviations, based on the photon-counting statistics of the signal and background. The vertical error bar represents the 1σ calibration uncertainty. b, Concurrent measurements of NO concentration (parts per 10^9) and relative ultraviolet intensity (UV) (250-400 nm).

tainty is an inescapable feature of all analytical methods. In Fig. 3, the upper and lower lines are drawn from the 1σ intercept uncertainties using the 1σ slope uncertainties. The vertical displacement of these lines gives the 1σ calibration uncertainty, which is $\sim 5 \times 10^5$ cm⁻³ for the concentration range occupied by the ambient data of Fig. 2. The total photon-counting uncertainty in the calibration is a function of the broad-band fluorescence level of the sampled air. This uncertainty (defined above) is shown as a horizontal error bar and is smaller than those in the hydrocarbon determination in this calibration, which are shown as vertical bars, based on error propagation through equation (3) and using a 2% uncertainty in the determination of the chromatographic peak heights. This calibration uncertainty can be improved in future measurements.

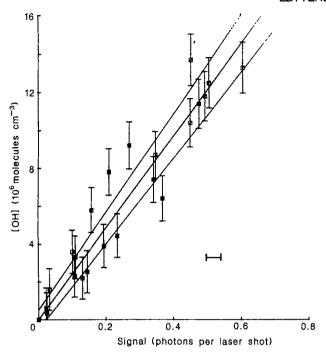

Fig. 3 FAGE calibration using OH-catalysed hydrocarbon consumption in a continuous-flow, ultraviolet-irradiated, Teflon-film bag. Vertical error bars are due to uncertainties in the measurement of hydrocarbon consumption. The horizontal error bar represents the (2σ) photon-counting statistics of the background and signal.

The detailed chemical composition of the air at our urban site is unknown, and its complexity precludes rigorous comparison with tropospheric chemical models. Nevertheless, the diurnal cycle exhibited on the relatively unpolluted day of 18 June (near the summer solstice) is similar to that predicted by clean-air photochemical models at ground level, 45° N latitude. Hydroxyl concentrations in clean air vary largely in response to diurnal variation in ultraviolet light intensity (Fig. 2b). Crutzen and Gidel¹² have calculated a July daytime average [OH] of 2×10^6 cm⁻³; Logan et al.¹³ predicted a diurnal cycle with a peak of $\sim 1.5 \times 10^6$ cm⁻³ at the lower light intensities and water vapour concentrations of the equinox. We used the mechanism and rate constants of ref. 13, with appropriate changes in ultraviolet light intensity and water vapour concentration, to find a maximum clean-air [OH] of 6×10^6 cm⁻³ summer solstice. Inclusion of our measured concentrations of NO, O₃, and H₂O reduces the calculated maximum OH concentration to 2×10^6 cm⁻³. No attempt is made here to include the non-methane hydrocarbon chemistry, which may alter the model predictions further. Graedel et al.14 predicted a peaksummer [OH] of 1.7×10⁶ cm⁻³ in an urban-air modelling study, and Calvert¹⁵ derived a value of ~2×10⁶ cm⁻¹ in an analysis of hydrocarbon consumption in the summer Los Angeles atmosphere. Our results are not inconsistent with global [OH] averages and distributions derived from the known sources and atmospheric distributions of CH₃CCl₃ (ref. 16) or ¹⁴CO (ref. 17).

Hydroxyl signals were detected during both nights, but were higher on the first. In contrast, [NO] was much higher on the second night (Fig. 2b). Although daytime photodissociation processes are thought to be the prime source of OH in both clean and polluted air, there are several mechanisms which could account for the presence of OH at night: (1) HO₂ is predicted to persist through the night in clean air at levels > 10⁶ molecules cm⁻³ (ref. 13), and mixing of such air with urban air containing NO could generate OH; (2) peroxynitrates serve as free-radical reservoirs which dissociate to generate OH precursors; (3) NO₃ can react with hydrocarbons or aldehydes to give other radicals. Although these sources may require the presence of NO to reduce precursor radicals (such as HO₂) to OH, NO also pro-

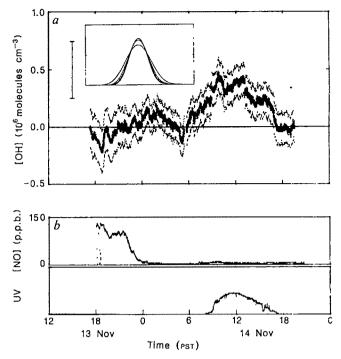

Fig. 4 Ambient [OH] (a) and related variables (b) during 13-14 November 1985. A 4-h averaging tme was used for [OH] because of its lower concentration and the higher background relative to the summer measurements; the relative ultraviolet intensity curve cannot be compared on an absolute basis with Fig. 2b; otherwise, as in Fig. 2. The inset shows the effect of several averaging intervals (1, 2, 4 h) on a diurnal [OH] profile generated by numerical integration of a clean-air mechanism.

vides a sink for OH, forming nitrous acid, which is stable in the dark. For a fixed precursor-free-radical source strength, nocturnal [OH] is expected to be inversely related to the NO concentration, consistent with the [OH] signals on the two nights.

Although the night-time OH signals exhibit adequate precision relative to photon-counting uncertainties, their magnitude lies within the calibration uncertainties of Fig. 3; thus, further nocturnal OH measurements are needed.

A second measurement was carried out on 13-14 November 1985, and the results are shown in Fig. 4. Due to lower signal level and higher background, a 4-h moving average is shown here—this will broaden the actual curve, as shown in the figure inset. Here it was necessary to shift the baseline by 2×10^5 cm ³ [OH] to compensate for an apparent negative offset. This offset was not present in the June data and, although of undetermined origin, it may be due to fluorescence of impurities in the modulating reagent. These data show a diurnal pattern similar to that of the summer data, but with a greatly reduced maximum concentration, presumed to be due in large part to reduced light intensity. The maximum concentration is again in agreement with clean-air chemical models, although this agreement may be fortuitous, given the actual composition of the urban air analysed.

The experiments reported here confirm the tropospheric presence of OH and its dependence on light intensity at concentrations in reasonable agreement with tropospheric chemical theory. The experiments do not yet explore the detailed photochemical mechanism that supports OH, which must be understood in order to predict the tropospheric effects of natural cycles and man-made pollution. Besides OH, a key species for this exploration is HO₂, which can also be determined by FAGE⁷. More rigorous comparison of these radical concentrations with clean-air atmospheric models can be achieved by refinement of the calibration of the FAGE instrument, its movement to sites truly representative of the clean troposphere, and the accumulation of data in different seasonal conditions. We

are combining the HO and HO2 procedures into a single instrument for the initiation of these experiments.

Structure determination of α -CrPO₄ from powder synchrotron X-ray data

J. Paul Attfield*‡, A. W. Sleight* & A. K. Cheetham†

Knowledge of the ordered atomic structures of crystalline materials is essential in many areas of science. Single-crystal X-ray diffraction is the technique most often used for both solving and refining crystal structures, but recently, powder diffraction methods have become increasingly important. Many structures have been successfully refined with powder data by using the Rietveld profile method1 to overcome the problem of overlapping Bragg peaks, but attempts to solve structures ab initio, which require a set of well-resolved Bragg intensities, have proved unsuccessful (with a few notable exceptions^{2,3}). However, a new generation of extremely high-resolution powder X-ray4 and neutron5 diffractometers now allows the ab initio determination of crystal structures from powder data (see ref. 6). As part of our study of the structural and magnetic properties of transition-metal phosphates^{7,8}, we present here the structure of \alpha-CrPO_4, solved from powder X-ray data obtained at the Brookhaven National Synchrotron Light Source, and confirmed by a Rietveld analysis of neutron data collected with the diffractometer Dla at the Institut Laue-Langevin, Grenoble.

Two isostructural modifications of $CrPO_4$ are known⁹. β -CrPO₄ is isostructural with CrVO₄¹⁰, and its atomic and spiral magnetic structure have recently been refined using low-temperature neutron data⁸. Above 1,175 °C, the light-green β phase transforms to the dark-blue α form, considered here. In order to compare the magnetic properties of the two polymorphs in detail, it is necessary to know the structure of α -CrPO₄, but neither this material, nor CrAsO₄¹¹, its only known isotype, has been prepared as single crystals. However, α-CrPO₄ is formed as a highly crystalline powder, making it a suitable candidate for study by high-resolution powder methods.

A polycrystalline sample of α-CrPO₄ was prepared by evaporating a solution containing equimolar quantitites of Cr(NO₃)₃·9H₂O (Fisher, certified) and (NH₄)₂HPO₄ (Fisher,

certified A.C.S.) until a green, glassy residue remained, and then heating this residue at 1,400 °C for 20 min. Prolonged heating of α -CrPO₄ above 1,175 °C was found to cause decomposition, although the material seems to be stable at ambient temperatures. The composition was confirmed by atomic absorption analysis: observed %Cr = 35.40, %P = 18.27; calculated %Cr = 35.36, % P = 21.08. The X-ray powder pattern agreed with that reported for α -CrPO₄¹², and all the reflections could be indexed on a body-centred orthorhombic cell with a = 10.405 Å, b =12.898 Å, c = 6.297 Å. We also observed the reflection condition h, k = 2n, making Imma the highest-symmetry space group possible.

Synchrotron X-ray data were collected on the X13A beam-line at the Brookhaven NSLS. X-rays with a wavelength of 1.323 Å from a perfect Ge(111) crystal monochromator, diffracting in the horizontal plane, impinged upon a flat-plate sample, and the scattering in the vertical plane was measured using a perfect Ge(220) analyser crystal and detector. A full description of the diffractometer and its resolution will be given elsewhere (D. E. Cox, L. P. Carduso, J. B. Hastings & L. W. Finger, in preparation). The sample was mixed with an equal volume of amorphous silica to minimize preferred orientation effects, and the sample tray was oscillated by 1° around the θ -axis to further reduce these effects and to increase the number of crystallites sampled by the beam. Data were collected from 10.50 to 64.50° 2θ at 0.01° intervals, with a count time of 2 s per step. The incident beam intensity was $\sim 5 \times 10^9$ photons s⁻¹, with the storage ring operating at 2.4 GeV and 50 mA.

All of the sharp diffraction peaks observed could be indexed

on the unit cell of α-CrPO₄ in space group Imma, and integrated intensities were obtained for 68 well-resolved peaks. After multiplicity and Lorentz corrections, these were used to generate a Patterson map which yielded two heavy-atom positions (Cr(2) and P(2)). These were used to start phasing the data, and the remaining atoms were located using several Fourier maps, bearing in mind geometric considerations. During this process-we realized that only 12 formula units were present in the unit cell, instead of 16 as had been proposed¹². The resulting coordinates were used as the starting model for a Rietveld analysis of the entire profile. A modified version of the standard Rietveld/ Hewat^{1,13} program was used¹⁴, with peaks shapes described by a 'pseudo-Voigt' function¹⁵. This approximates the convolution of gaussian (instrumental resolution) and lorentzian (sample broadening) functions. However, variations in peak shape and poor counting statistics gave a relatively poor fit $(R_{WP} = 24.1\%)$, and did not improve the structural model $(R_{\text{NUC}} = 11.8\%)$; R_{WP} and R_{NUC} are defined in reference (1).

To obtain a better refinement of the structure, a second set of synchrotron data was collected from the same α -CrPO₄/silica mixture, placed in a glass capillary tube (1.0 mm radius) which was rotated around the θ -axis. This reduces preferred orientation effects more effectively than the rocking flat-plate method used above. The region around each Bragg peak position was counted for 4s per 0.01° step. The longer count time and an increased beam current of 100 mA gave better statistics on the diffraction intensities than those of the first data set. The data were corrected for capillary absorption and the above starting model was refined using the same Rietveld program. A significantly better fit was obtained ($R_{\rm WP}$ =16.9%) and the quality of the structure also improved ($R_{\rm NUC}$ =7.0%). The results of this refinement are given in Table 1, and the observed, calculated, and difference profiles are shown in Fig. 1a.

In addition, during our studies of the low-temperature magnetic properties of α -CrPO₄, a set of neutron data was collected using diffractometer D1a at the ILL, Grenoble. The scattering from a sample of pure α -CrPO₄, held in a vandium can in a cryostat at 25 K, was measured in the range 6-136° 2θ in 0.05°

steps at a mean neutron wavelength of 1.95Å. A Rietveld analysis of this data set, which contains no magnetic diffraction peaks, gave an excellent fit ($R_{\rm WP}=10.4\%$), as shown in Fig. 1b, confirming the structure and showing that there is no evidence for the symmetry of the structure being lower than Imma. The refined coordinates are given in Table 1 for comparison with the X-ray values; a fuller discussion and more details of these refinements will be presented in a future publication.

The structure of α -CrPO₄ consists of an infinite network of linked CrO₆ octahedra and PO₄ tetrahedra. Pairs of edge-sharing Cr(2)O₆ octahedra, interconnected by P(2)O₄ tetrahedra, form sheets in the b-c plane (Fig. 2). These are linked to each other

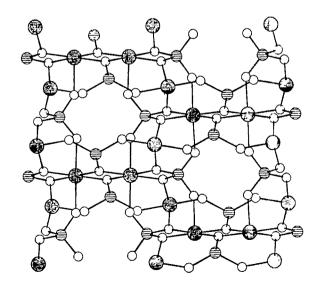

Fig. 2 View of the (100) plane of α -CrPO₄ (y horizontal, z vertical), showing the coordination of the bidentate phosphate groups to edge-sharing pairs of CrO₆ octahedra (Cr, large shaded circles, P, medium striped circles; O, small open circles).

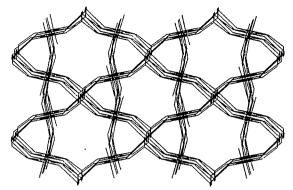

Fig. 3 Stick model of the structure of α -CrPO₄ close to (010), showing the channels parallel to b. x is near-horizontal and z is vertical.

by chains of alternating Cr(1)O₆ octahedra and P(1)O₄ tetrahedra running parallel to b, resulting in the formation of large channels in this direction (Fig. 3). An interesting feature of this structure is the sharing of a common edge between a P(2)O₄ tetrahedron and a Cr(2)O₆ octahedron, both of which are distorted, resulting in a short non-bonding Cr-P distance of 2.68(1) Å and an O-O contact of 2.33(2) Å. The bond distances given in Table 1 and the bond angles (which can be obtained from the authors) are similar to those in β-CrPO₄¹¹ and other chromium phosphates. Although the $3d^3$ electronic configuration of the Cr3+ ion favours regular octahedral coordination, the connectivity of this framework necessarily gives rise to distortions of the polyhedra.

The fact that neither α-CrPO₄ nor CrAsO₄ is thermally stable under the conditions of their formation implies that these compounds are metastable. The persistence of these materials at ambient temperatures may be due to the well-known kinetic

inertness of octahedral Cr3+ towards the dissociative ligand exchange that must accompany their decomposition. This also explains why no other trivalent metal phosphate, nor any other ABO₄ compound, has been found to adopt this structure. The cause of this instability is presumably the strained planar fourmembered ring resulting from the bidentate phosphate group. The intra-annular angles around Cr(2), P(2) and the two O(2)atoms are 72, 95 and 97° respectively, showing that all are highly distorted from their preferred geometries.

This work was made possible by the excellent instrumentation and software on the X13A beam-line at the National Synchrotron Light Sourse, Brookhaven National Laboratory, which is supported by the U.S. Department of Energy, Divisions of Materials Sciences and Chemical Sciences. In particular, we thank, Drs D. E. Cox (BN Laboratory) and L. W. Finger (Carnegie Institute) for their efforts in making this a highly valuable facility. The authors also wish to thank SERC for the provision of neutron facilities and a studentship for J.P.A., and Drs J. C. Calabrese, C. J. Eyermann, R. Fischer and R. L. Harlow for assistance with local computer programs.

Formation of ultra-fine amorphous alloy particles by reduction in aqueous solution

Jacques van Wonterghem*, Steen Mørup*, Christian J. W. Koch†, Stuart W. Charles‡ & Steven Wells‡

* Laboratory of Applied Physics II, Technical University of Denmark, DK-2800 Lyngby, Denmark

† Chemistry Department, Royal Veterinary and Agricultural University, DK-1871 Frederiksberg C, Denmark

‡ Department of Physics, University College of North Wales, Bangor LL57 2UW, UK

Amorphous alloys are normally prepared as thin ribbons or films by the liquid quench technique or by vapour deposition. Recently we have shown that ultra-fine amorphous Fe-C alloy particles can be prepared by thermal decomposition of Fe(CO), in an organic liquid; that is, by a chemical reaction. Here we report the preparation of small alloy particles by reduction of metal ions by KBH4 in aqueous solutions. Mössbauer and X-ray diffraction studies show that the particles are amorphous. The amorphous phase is formed because the chemical reaction takes place below the glass transition temperature and because boron atoms are present in the particles. The method may be used for the large-scale production of ultra-fine amorphous alloy particles, which may have applications in ferrofluids, magnetic memory systems and catalysis.

Reduction of metal ions in aqueous solutions by use of KBH₄ has been described elsewhere^{2,3}. Oppegard et al.³ found that reduction of solutions of FeSO₄ or mixtures of FeSO₄ and CoCl₂ by KBH₄ resulted in the formation of small magnetic particles. X-ray diffraction studies of the particles revealed the presence of diffuse lines corresponding to α -iron.

In the present study we have prepared similar material by adding drops of an aqueous solution of FeSO₄ and CoCl₂ with an Fe: Co molar ratio of 7:3 to an excess of 1 M KBH₄. The solutions were mixed by vigorous stirring and the black precipitate was washed in water and then in acetone. Mössbauer spectra were obtained using a constant-acceleration spectrometer with a source of ⁵⁷Co in rhodium. X-ray diffractographs were obtained with a powder diffractometer equipped with a diffracted-beam graphite monochromator. Magnetic measurements were made with a vibrating-sample magnetometer. The samples were studied before and after annealing at 725 K for 2 h in H₂.

Figure 1 shows room-temperature Mössbauer spectra of the sample. Before annealing, the spectrum exhibits very broad lines, indicating a distribution in magnetic hyperfine fields. The isomer shift relative to α -Fe is 0.19 mm s⁻¹ and the quadrupole

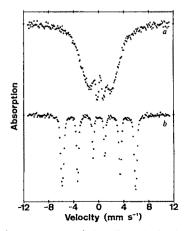

Fig. 1 Mössbauer spectra of the alloy obtained at room temperature: a, before annealing; b, after annealing at 725 K.

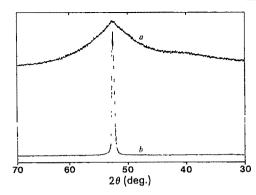

Fig. 2 X-ray diffractographs of the alloy: a, before annealing; b, after annealing at 725 K. The diffractographs were obtained using Co K, radiation.

shift is negligible. The average magnetic hyperfine field is ~18 T, which is considerably smaller than those of crystalline Fe-Co alloys. The magnetic hyperfine field is also smaller than those of amorphous (Fe_{1-x}Co_x)₈₀B₂₀ alloys produced by the liquid quench technique⁴, but is similar to those of amorphous Fe-B alloys with higher boron content.

After annealing, the Mössbauer lines are considerably sharper and the average magnetic hyperfine field increases to 36.5 T, whereas the isomer shift decreases to $\sim 0.03 \text{ mm s}^{-1}$. These parameters are close to those of a crystalline Fe-Co alloy with an Fe:Co ratio of 7:3 (ref. 6). Thus the Mössbauer results indicate that amorphous Fe-Co-B particles are formed during the preparation and that these particles crystallize during annealing at 725 K.

Further evidence for this conclusion is obtained from the X-ray diffraction studies (Fig. 2). Before annealing, the diffractograph shows only a very broad line, indicating the absence of crystalline phases⁷. After annealing, a sharp diffraction line is observed corresponding to a well-crystallized Fe-Co alloy.

Chemical analysis of the particles showed that the composition of the amorphous alloy is Fe₄₄Co₁₉B₃₇; that is, the ratio between iron and cobalt atoms is identical to that in the original aqueous solution. The relatively high boron content explains the low value of the magnetic hyperfine field.

The saturation magnetization of the amorphous Fe₄₄Co₁₉B₃₇ alloy is 89 J T⁻¹ kg⁻¹. After annealing it rises to 166 J T⁻¹ kg⁻¹ which is below the value of 240 J T⁻¹ kg⁻¹ for a pure crystalline Fe₇₀Co₃₀ alloy. The lower value is presumably due to the presence of boron in the alloy or in a separate phase. Infrared spectroscopy of the annealed samples indicated the presence of a boron oxide.

From the Mössbauer and X-ray diffraction spectra it can be concluded that the material formed by reduction of iron and cobalt ions in solution is an amorphous alloy which crystallizes during annealing at 725 K. We have also studied samples prepared from solutions with iron and nickel or with iron alone, and the Mössbauer and X-ray diffraction results for these samples are similar to those of the Fe-Co-B alloy particles. Chemical analysis yielded the compositions Fe₃₇Ni₂₈B₃₄ and Fe₆₂B₃₈, respectively. Electron microscopy of the samples revealed that the particle dimensions are in the range 10-100 nm, depending on the preparation conditions.

Because amorphous alloys are stable only below the glass transition temperature, Tg, a requirement for the formation of amorphous alloy particles by chemical methods is that the chemical reaction takes place below T_g . For pure iron, T_g is far below room temperature; therefore, one or more other elements must be present in order to stabilize the amorphous structure at room temperature. In the present particles, boron atoms from KHB₄ have entered into the alloy particles as a stabilizing element during the chemical reaction.

When amorphous alloys are prepared by the conventional liquid quench technique it is essential that the material is cooled

very rapidly from the melting temperature to a temperature below $T_{\rm g}$. This is because the alloys crystallize easily between these temperatures. Therefore, when using this technique, a composition close to the eutectic one facilitates the formation of an amorphous phase. However, when producing amorphous alloys by chemical methods at low temperature the only restriction is that the reaction take place at a temperature below $T_{\rm g}$. It is therefore likely that these chemical techniques may allow the formation of amorphous alloys with compositions which cannot easily be produced by the liquid quench technique.

Financial support from the Danish Technical Research Council is gratefully acknowledged.

Latter-day origin of diamonds of eclogitic paragenesis

Stephen H. Richardson

Laboratoire de Geochimie et Cosmochimie, Institut de Physique du Globe de Paris, 4, place Jussieu. 75252 Paris Cedex 05, France

Syngenetic mineral inclusions in diamonds provide the best means of determining their origin. Among such inclusions, the peridotitic paragenesis of olivine, orthopyroxene and chrome-pyrope garnet is on average far more abundant than the eclogitic paragenesis of pyrope-almandine garnet and omphacitic clinopyroxene 1-3. Diamonds of peridotitic paragenesis from the ~100-Myr-old Kimberley and Finsch kimberlites in southern Africa were previously shown to have originated in 150-200-km-thick lithosphere beneath the Kaapvaal craton ~3,300 Myr ago^{4,5}. At a few localities, such as the Premier kimberlite in southern Africa and the Argyle lamproite in northwestern Australia, diamonds of eclogitic paragenesis predominate⁶⁻⁸, allowing recovery of sufficient material for complementary analysis, the results of which are reported here. Eclogitic garnet and clinopyroxene inclusions in Premier and Argyle diamonds yield Sm-Nd isochron ages of 1,150 and 1,580 Myr respectively, compared with host diatreme emplacement ages^{9,10} of 1,100-1,200 Myr. Eclogitic inclusion ages and precursor isotopic signatures indicate a second genetically distinct origin of diamonds, apparently related in time and space to kimberlite or lamproite magmatism.

The Premier kimberlite is located in the interior of the Archaean Kaapvaal craton and is the only Precambrian diatreme in southern Africa currently exploited for diamonds⁶. It has been difficult to determine the precise age of emplacement because of the altered nature of the kimberlite matrix material, thermal effects of a cross-cutting sill and absence of zircons for U-Pb analysis. Nevertheless, a phlogopite Rb-Sr age of ~1,250 Myr has been available for some time11, together with a minimum age of 1,100 Myr dictated by the cross-cutting sill¹². Then, following early work by Welke et al.¹³, Kramers⁹ obtained a model Pb age of ~1,200 Myr for presumed sulphide inclusions in Premier diamonds. More recently, two essentially identical Rb-Sr and Sm-Nd ages of 1,180±30 Myr have been obtained using diopside and garnet megacrysts14,15

The Argyle lamproite is located in the Proterozoic Halls Creek mobile zone adjacent to the Kimberley craton in northwestern

uncertainties in concentrations (ignoring small-sample weighing errors) indicated by number of significant digits.

† Present-day ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd ratios normalized to 0.70800 and 0.51264 for standards E & A SrCO₃ and BCR-1, respectively. In-run precision given by errors $(2\sigma_{\text{mean}})$ corresponding to least significant digits. Initial ratios (denoted by subscript i) calculated for Argyle and Premier diamond crystallization ages of 1,580 and 1,150 Myr, respectively, using $\lambda_{\text{Rb}} = 1.42 \times 10^{-11} \text{ yr}^{-1}$ and $\lambda_{\text{Sm}} = 6.54 \times 10^{-12} \text{ yr}^{-1}$.

‡ Selected from -7+5 diamond sieve fraction (1.8-2.5 mm diameter) of general mine production.

§ Argyle composites: ~460 deep-orange garnets (d.o.gar) and 190 pale-orange garnets (p.o.gar) (avg. wt 10 μg); ~70 pale-green clinopyroxenes (p.g.cpx) (avg. wt 3 μg).

Premier composites: ~175 d.o.gar and 325 p.o.gar (avg. wt 15 μg); ~250 p.g.cpx (avg. wt 7 μg).

Australia, and is the first diamondiferous diatreme in the region to be brought into commercial production¹⁶. A preliminary phlogopite Rb-Sr age of 1.130 Myr for the magmatic phase of the intrusion¹⁰ is consistent with the geochronology of the host country rock succession, which has a maximum age of \sim 1,200 Myr (refs 16-18).

Premier diamond inclusion mineralogy, abundances and major element compositions are described in detail in ref. 6. The eclogitic assemblage of sulphides, orange garnet, pale-green clinopyroxene and rare kyanite and coesite comprises ~60% of inclusions, with the peridotitic assemblage of sulphides, olivine, orthopyroxené, minor purple garnet and chromite, and rare bright-emerald-green clinopyroxene accounting for the remainder⁶. Argyle diamond inclusion characteristics are outlined in refs 7 and 8. Here the eclogitic assemblage of orange garnet, pale-green clinopyroxene, sulphides, and minor kyanite, rutile and coesite is even more dominant, accounting for up to 90%

To study the age and origin of these assemblages, the most suitable radiogenic isotope systems are Sm-Nd, Rb-Sr and U-Th-Pb. Although sulphides, the most likely carriers of Pb (ref. 9), appear to be a major inclusion phase at Premier (and to a lesser extent at Argyle), they are difficult to characterize and cannot easily be assigned to either paragenesis^{6,8}. In contrast, the different garnets and clinopyroxenes, the major carrier phases of Nd and Sr, are relatively easily distinguished on the basis of colour, especially after they have been broken out of the host diamonds. This is important because small inclusion size, coupled with Nd concentrations of only a few p.p.m., necessitates the combining of cogenetic inclusions of a given phase⁴. Eclogitic garnets and clinopyroxenes selected for each composite sample in Table 1 were recovered from diamonds bearing monomineralic inclusions, except for scarce Argyle clinopyroxenes, most of which came from diamonds also containing garnets. Touching clinopyroxene and garnet inclusions, which at mantle temperatures would tend to equilibrate continuously with each other by interdiffusion, are rare and such specimens were excluded. Otherwise, Nd and Sr diffusion through intervening diamond is assumed to be negligible⁴. Eclogitic garnets were subdivided on the basis of colour into deep-orange and pale-orange fractions, a distinction which is more clearly developed at Argyle than at Premier. No convincing examples of a pale-orange garnet-clinopyroxene pair were found in available bimineralic-inclusion-bearing diamonds, indicating that pale-orange garnets probably did not coexist with a separate clinopyroxene phase, as also suggested by Sm/Nd partition relationships. Small-sample preparation tech-

niques and mass spectrometric facilities for determination of Sm, Nd, Rb and Sr concentrations and isotope ratios (Table 1) are the same as those used by Richardson et al.4 except for a new (1985) clean lab (belonging to S.R. Hart) and an improved Sr loading technique with higher ion yield19

Nd and Sr concentrations in Argyle inclusions are, on average, five times higher than those in their Premier counterparts, while Sm/Nd ratios are lower by a factor of 1.4 (Table 1). The Sm/Nd ratios, particulary those for garnet (0.5-0.8), are sufficient to produce substantial increases in the 143Nd/144Nd ratio on a timescale of 1,000 Myr, whereas the Rb/Sr ratios are all extremely low (0.0002-0.002), resulting in barely significant increases in 87 Sr/ 86 Sr ratio. Thus, 87 Sr/ 86 Sr ratios can be used to verify the cogeneticity of garnet and clinopyroxene inclusions from separate diamonds, which have been combined and paired

for the derivation of Sm-Nd isochron age relationships.

Present-day ¹⁴⁷Sm/¹⁴⁴Nd and ¹⁴³Nd/¹⁴⁴Nd ratios (Table 1) are plotted on a Sm-Nd isochron diagram in Fig. 1. The Argyle

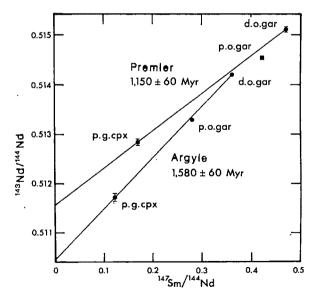

Fig. 1 Sm-Nd isochron diagram for eclogitic garnet and clinopyroxene inclusions in Argyle and Premier diamonds. Measurement errors $(2\sigma_{mean})$ are indicated except where smaller than the size of plotted points. Ages are for deep-orange garnetpale-green clinopyroxene pairs, using $\lambda_{Sm} = 6.54 \times 10^{-12} \, \text{yr}^{-1}$. Assigned errors are derived from the maximum and minimum slopes allowed by measurement errors.

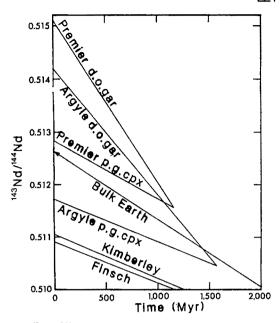

Fig. 2 ¹⁴³Nd/¹⁴⁴Nd evolution diagram, showing curves for eclogitic garnet and clinopyroxene inclusions in Argyle and Premier diamonds. Curves are constructed from measured ¹⁴³Nd/¹⁴⁴Nd and ¹⁴⁷Sm/¹⁴⁴Nd ratios and terminate at the times of diamond crystallization from Fig. 1. Curves for peridotitic garnet inclusions in Kimberley and Finsch diamonds and the bulk Earth curve are from Richardson et al.⁴ and references therein.

deep-orange garnet-clinopyroxene pair defines an age of 1,580 ± 60 Myr, with assigned error derived from the maximum and minimum slopes allowed by $2\sigma_{mean}$ measurement errors (Table 1). The Argyle pale-orange garnet with intermediate Sm/Nd ratio falls below and outside the analytical errors of this twopoint isochron. In addition, the initial 87Sr/86Sr ratios of the deep-orange garnet and clinopyroxene are within error of each other (0.7059), while that of the pale-orange garnet is slightly but significantly lower (0.7054). In analogous fashion, the Premier deep-orange garnet-clinopyroxene pair defines an age of 1,150 ± 60 Myr, with the pale-orange garnet again having an intermediate Sm/Nd ratio and lying below the two-point iso-chron. In this case, all three initial ⁸⁷Sr/⁸⁶Sr ratios are slightly but significantly different (d.o.gar: 0.7026; p.g.cpx: 0.7022; p.o.gar: 0.7023). However, the deep-orange garnet Sr concentration (1.7 p.p.m.) and amount (4 ng) were the lowest measured, and minor sample impurity may have affected the measurement. Thus, the clinopyroxene Sr isotope ratio is considered to be more representative.

The Argyle eclogitic diamond inclusion age of 1,580 Myr is ~450 Myr greater than the host lamproite emplacement age10 of 1,130 Myr, and closer to the ~1,800 Myr age of stabilization of the surrounding Halls Creek mobile zone¹⁶. Although this indicates that Argyle eclogitic diamonds are xenocrysts in the host lamproite, it does not preclude an original phenocrystal relationship with similar small-volume mantle magmatism ~450 Myr earlier and subsequent lithospheric storage. In contrast, the Premier eclogitic diamond inclusion age of 1,150± 60 Myr is within error of the preferred host kimberlite age^{14,15} of 1,180 ± 30 Myr, and in agreement with the sulphide inclusion Pb model age of ~1,200 Myr obtained by Kramers⁹. There is thus no resolvable time difference between Premier eclogitic diamond crystallization and host kimberlite emplacement. However, the aggregation state of nitrogen in Premier eclogitic diamonds³⁰ requires mantle storage for a finite time interval (~1-10 Myr at 1,270 °C, the crystallization temperature⁶; T. Evans and J. W. Harris, personal communication) before removal to the surface.

Further evidence relating to eclogitic diamond origin is pro-

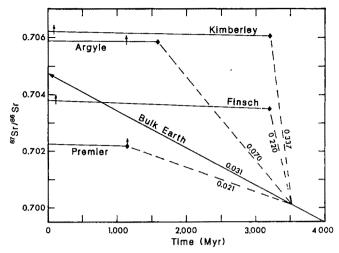

Fig. 3 87Sr/86Sr evolution diagram, showing curves for eclogitic garnet and clinopyroxene inclusions in Argyle and Premier diamonds. Curves are constructed from measured 87Sr/86Sr and 87Rb/86Sr ratios and terminate at the times of diamond crystalization (diamond symbols) from Fig. 1. Times of host diatreme emplacement are also indicated (vertical arrows). Garnet and clinopyroxene Rb/Sr ratios are so low that the corresponding evolution curves are virtually horizontal. Hypothetical precursor evolution curves (dashed) emanating from the bulk Earth at 3,500 Myr and corresponding time-integrated Rb/Sr ratios are shown for reference. Curves for peridotitic garnet inclusions in Kimberley and Finsch diamonds and the bulk Earth curve are from Richardson et al.14 and references therein.

vided by the initial Nd and Sr isotopic ratios of the inclusions at the time of their crystallization and encapsulation by diamond (Table 1). These are plotted in Nd and Sr isotope evolution diagrams (Figs 2, 3), for comparison with those of potential precursors. The Premier deep-orange garnet-clinopyroxene pair (and to a lesser extent the pale-orange garnet) has a substantially higher initial Nd isotopic ratio ($\varepsilon_{Nd} = +8$) and lower initial Sr isotopic ratio (0.70217) than those of the bulk Earth at 1,150 Myr. These are the isotopic characteristics of asthenospheric upper mantle such as that now giving rise to the most depleted (low time-integrated Nd/Sm and Rb/Sr) mid-ocean-ridge basalts (MORB). Similar, although less extreme, initial Sr and/or Nd isotopic ratios have previously been measured in Premier clinopyroxene inclusions^{13,9}, carbonatite¹³ and megacryst garnet and diopside¹⁵, although apparently not in kimberlite matrix material²⁰. In addition, the majority of Premier eclogiticinclusion-bearing diamonds have δ^{13} C values of -3 to -6 (ref. 21), consistent with a MORB-type mantle carbon source (see, for example, ref. 22) and within the relatively narrow range of -1 to -8 observed for peridotitic-inclusion-bearing diamonds worldwide23. In contrast, the Argyle deep-orange garnetclinopyroxene pair (and similar pale-orange garnet) has initial Nd and Sr isotopic ratios ($\varepsilon_{\rm Nd} = -3$; $^{87}{\rm Sr}/^{86}{\rm Sr}_{\rm i} = 0.7059$) respectively lower and higher than those of the bulk Earth at 1,580 Myr (Figs 2, 3). These isotopic characteristics are indicative of a mildly enriched (high time-integrated Nd/Sm and Rb/Sr) component (or mixture of depleted and highly enriched components) akin to that found in old subcontinental lithosphere²⁴ and manifest in young West Kimberley lamproites^{25,26}, although the initial ratios for the host Argyle lamproite itself have yet to be determined. Eclogitic-inclusion-bearing diamonds from Argyle have δ^{13} C values of -8 to -16 (E. M. Galimov, personal communication), clearly distinct from those at Premier but within the range of values (+2 to -25) for eclogitic-inclusion-bearing diamonds worldwide²³.

The asthenospheric isotopic signature and almost immediate removal to the surface of Premier eclogitic diamonds contrasts with the lithospheric Nd and Sr component, ¹³C depletion and significant lithospheric storage of their Argyle counterparts.

Evidently, eclogitic-inclusion-bearing diamonds do not have a unique age or precursor but appear to be related in time and space to kimberlite or lamproite magmatism. In addition, these latter-day diamonds of eclogitic paragenesis are distinct in origin from those of the dominant peridotitic paragenesis formed ~2,000 Myr earlier in residual yet highly enriched Archaean lithosphere⁴ (Figs 2, 3). Further study of eclogitic-inclusionbearing diamonds from Cretaceous eruptives such as Orapa, in the Archaean Limpopo mobile belt²⁷, and Monastery, where garnets with high-pressure phase chemistry have recently been described²⁸, should help to elucidate this distinction and constrain global models of diamond genesis²⁹.

De Beers Consolidated Mines is acknowledged for providing specimens and support for the analytical phase of this work; the initiative of J. B. Hawthorne, expert supervision of J. W. Harris and efforts of J. Scott, A. van Niekerk and V. Anderson are appreciated. Special thanks to S. R. Hart, K. Burrhus, L. Gulen and J. Alley at MIT, where S.R.H.'s isotope lab is funded by NSF grant EAR83-08809. Continuing support from C. J. Allègre at IPG is gratefully acknowledged.

Upper mantle oxygen fugacity recorded by spinel lherzolites

Glen S. Mattioli & Bernard J. Wood

Department of Geological Sciences, Northwestern University, Evanston, Illinois 60201, USA

The oxygen fugacities (f_{O},s) recorded by rocks from the Earth's upper mantle have been the subject of much recent study and controversy1-7. Discussion has been stimulated by reported differences of several orders of magnitude between measurements made by different methods (Fig. 1). Oxygen fugacity is an important parameter because, together with temperature, pressure and composition, f_{O} , controls the petrogenesis of mantle-derived magmas, affects the composition and speciation of mantle fluids, and is an initial input into geochemical models of the evolution of the Earth's crust, mantle and hydrosphere. Here we report the determination of the f_{O_2} recorded by upper mantle spinel-lherzolite xenoliths entrained in alkaline magmas. This was done by experimentally calibrating the activity of the Fe₃O₄ (magnetite) component in MgAl₂O₄-rich synthetic spinel and applying these data to calculate thermobarometric f_{O} , s for the three-phase assemblage olivine-orthopyroxene-spinel. Results for appropriate model xenolith compositions, corrected to 15 kbar total pressure⁸ and plotted in temperature- f_{O_2} space, fall at or above the synthetic quartz-fayalite-magnetite buffer (Fig. 3). In contrast to earlier studies^{2,3}, we conclude that the shallow upper mantle does not retain an f_{O_2} signature of equilibrium with the metallic core, and that gaseous species in the C-H-O system will be dominated by CO₂ and H₂O (refs 9, 10), rather than CH₄ and H₂.

The f_{O_2} recorded by mantle spinel may be determined from either thermobarometric⁵⁻⁷ or intrinsic¹⁻⁴ measurements. In the thermobarometric method, a heterogeneous equilibrium, such as

$$= 6 \text{ Fe}_2 \text{SiO}_4 \text{ (in olivine)} + \text{O}_2 \tag{1}$$

is used together with analysed compositions of the relevant mineral phases and experimentally calibrated activity-composition relationships to yield an estimate of the f_0 , at constant

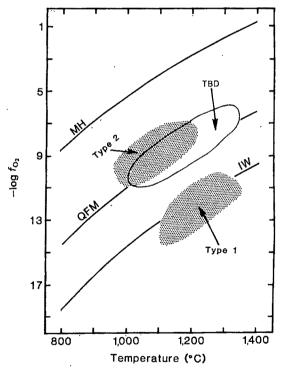

Fig. 1 Compilation of previous estimates of upper mantle f_{O_2} versus temperature at 1 atm total pressure. The stippled regions represent intrinsic measurements of type 2 spinel-lherzolite whole rocks and ilmenite separates⁴ ('Type 2'), and of type 1 spinel separates from spinel-lherzolite xenoliths²⁻⁴ ('Type 1'). The unshaded area ('TBD') represents thermobarometric data from ilmenite-bearing mantle nodules⁵, ilmenite-spinel intergrowths⁶ and terrestrial basalts7.

temperature and pressure⁵⁻⁷. In contrast, the intrinsic method is based on determination of single-phase, homogeneous defect equilibria¹¹. It is assumed that the concentration of defects (vacancies in the octahedral sublattice of the spinel phase, for example) is sufficient to buffer the f_{O_2} of a small volume of inert gas at the equilibrium value, which is measured using a zirconia solid electrolyte.

Figure 1 shows previous estimates of upper mantle f_{Ω} , together with the standard synthetic Fe-bearing buffers magnetitehaematite (MH), quartz-fayalite-magnetite (QFM) and ironwüstite (IW) at 1 atm total pressure. The oxygen fugacity estimates fall into two groups. First, thermobarometric estimates⁵⁻¹ for ilmenite-bearing mantle nodules and megacrysts, spinelilmenite intergrowths in nodules found in kimberlite, and Fe-Ti oxides in terrestrial basalts, all group within 1.5 log units of QFM. Second, intrinsic data, collected using a solid zirconia electrolyte technique, show a wide range of apparent f_{O_2} s. Early work on olivine phenocrysts from an oceanic tholeiite pillow¹ and the more recent data²⁻⁴ on spinel separates from type 1 lherzolite xenoliths (Cr-rich suite, Basaltic Volcanism Study Project¹²) are grouped near or below IW. This is up to four orders of magnitude more reducing than the f_{O_2} estimates calculated by thermobarometric methods on the same rocks. Intrinsic measurements of ilmenite separates and type 2 (Cr-poor suite) whole rocks, however, fall at or above QFM⁴. It is unclear why there is such a disparity between the intrinsic f_{O_2} s of type 1 and type 2 spinel lherzolites, as the spinels contain very similar amounts of Fe₃O₄. Intuitively, the similar mole fractions of Fe₃O₄ imply similar Fe₃O₄ activities and, from equilibrium (1), similar f_{O_2} s. In an effort to resolve the discrepancy, we present an experimentally calibrated data set for dilute magnetite activities on the pseudo-binary spinel join Fe₃O₄-MgAl₂O₄, at 800, 900 and 1,000 °C and 1 atm total pressure. This system approximates closely the compositions of spinels from the type 2 Iherzolite suite, and these data, when combined with published experiments on Cr-Al-Fe mixing in spinel¹³⁻¹⁵, may be used to calculate thermobarometric f_{O_2} s for most mantle-derived spinels.

Synthetic spinel solid solutions were prepared initially at 1400-1500 °C in air at 1 atm. Under these conditions, the spinels crystallize in the ternary system MgAl₂O₄-Fe₃O₄-γ-Fe_{8/3}O₄; that is, a small amount of defect spinel (maghemite) is present. Defect spinels were re-equilibrated in a variety of reducing conditions, such as in a 1.0% CO/Ar atmosphere or in a ${\rm CO/CO_2}$ gas mix with an $f_{\rm O_2}$ of 10^{-8} at 1,000 °C, and at 1,400 °C in an atmosphere with $f_{\rm O_2} = 10^{-4}$. Ammonium metavanadate titration was used to determine Fe(II)/Fe(III) ratios of selected products. The reducing environments yielded spinels with slightly different defect concentrations; nevertheless, these spinels (between 2 and 20 mol% Fe₃O₄) are essentially stoichiometric within the analytical uncertainty of ~2 mol%. In addition, the spinels were checked for crystallinity and homogeneity by X-ray diffraction, and optical and electron microscopy. Complete details of synthesis conditions, analysis methods, and defect-molar volume relations will be presented elsewhere³¹.

Magnetite activity was measured by mixing haematite with the spinel solid solutions and determining f_{O_2} as controlled by the equilibrium:

$$4 \text{ Fe}_3\text{O}_4 \text{ (in spinel)} + \text{O}_2 = 6 \text{ Fe}_2\text{O}_3 \text{ (in haematite)}$$
 (2)

We employed an yttria-stabilized-zirconia solid-electrolyte oxygen sensor to measure the shift in f_{O_2} relative to the MH buffer. At constant temperature and known Fe₃O₄ and Fe₂O₃ concentrations in the spinel and orthorhombic phases, respectively, the magnetite activity was given directly by the e.m.f. of the zirconia cell relative to a gas of known f_{O_2} . Al₂O₃ solubility in the haematite phase was modelled using published data¹⁶. At fixed Fe₃O₄ mole fraction, spinels synthesized under oxidized and various reduced conditions yielded the same Fe₃O₄ activity. This implies that the amount of γ -Fe_{8/3}O₄ component in the spinel phase must closely approximate the equilibrium concentration at the temperature and f_{0} , of the experiment. Equilibrium was demonstrated by in situ addition or subtraction of oxygen from the sample (coulometric titration) and verification that the e.m.f. was affected by these perturbations. The sample usually approached equilibrium fairly quickly after perturbation, so that the variation in e.m.f. with time became negligible within an

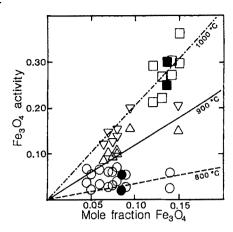

Fig. 2 Experimentally calibrated activity data for the Fe_3O_4 component in the spinel phase, plotted against the mole fraction of Fe_3O_4 component in MgAl₂O₄-rich synthetic spinel at 800, 900 and 1,000 °C (circles, triangles and squares, respectively) and 1 atm total pressure. Open symbols represent approach to equilibrium from high and low f_{O_2} with spinels synthesized in reducing conditions; shaded symbols are for runs with spinels synthesized in air. The size of the symbols reflects the approximate cumulative experimental uncertainty.

hour at 900 °C. X-ray diffractograms were obtained for all run products, to ensure that both phases were present and to determine the final spinel and haematite compositions.

Figure 2 shows the results of our activity measurements, as a plot of the reversed magnetite activities against the final spinel phase composition, determined using X-ray diffraction. We include experiments with spinel solid solutions made in the various reduced conditions as well as two runs with spinels made in air. The size of the symbols represents the approximate cumulative uncertainty for each reversal bracket. At each composition, the pair of symbols represents approach to equilibrium from high (lower symbol) and low (upper symbol) f_{O} . Note that our experiments are in the composition and temperature range appropriate for Cr-free mantle spinels. Our observation of increasing magnetite activity with increasing temperature at constant composition is probably due to changes in the equilibrium ordering state of the mixed spinels relative to the pure magnetite standard state¹⁷. This behaviour persists across the entire Fe₃O₄-MgAl₂O₄ join at 900 and 1,000 °C. We have used approximate linear (Henry's law) fits to the dilute magnetite activites (Fig. 2) in order to estimate upper mantle f_{O_2} . The fit lines are calculated from the equation

$$A_{\text{Fe}_3\text{O}_4} = (\alpha + \beta T) X_{\text{Fe}_3\text{O}_4} \tag{3}$$

where $X_{\text{Fe}_3\text{O}_4}$ and $A_{\text{Fe}_3\text{O}_4}$ are the mole fraction and activity of magnetite in spinel, $\alpha = -6.5 \pm 0.5$, $\beta = 8.5 \pm 0.5 \times 10^{-3}$, and T is temperature in °C.

Upper mantle f_{O_2} recorded by spinel-lherzolite xenoliths, the three-phase assemblage spinelcontain orthopyroxene-olivine, may now be calculated thermobarometrically from equilibrium (1). Fe₃O₄ activity was taken from equation (3), with Fe₂SiO₄ and FeSiO₃ activities and standard-state data from the literature^{18,19,32}. The Mg number $(Mg^{2+}/(Mg^{2+}+Fe^{2+}))$ of the silicate phases was fixed at 0.90, and the spinel phase composition was varied between 0.01 and 0.10 mole fraction Fe₃O₄ component. The latter range corresponds to the approximate limits observed by electron microprobe, wet chemistry and Mössbauer spectroscopy for spinel in mantle-derived spinel-lherzolite xenoliths. Figure 2 shows the results of these calculations as a temperature-log $f_{\rm O_2}$ plot at 15 kbar total pressure. Pressure-corrected Fe buffers are also included for reference. The f_{O_2} s shown in Fig. 3 were calculated at 15 kbar pressure using a ternary-spinel molar volume

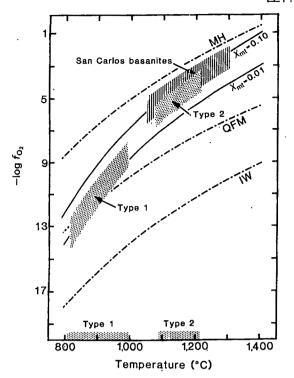

Fig. 3 Thermobarometric spinel data at 15 kbar total pressure. Solid lines are the loci of $(\log f_{O_2}, T)$ data calculated from equilibrium (1) for magnetite mole fractions ($X_{\rm mt}$) of 0.01 and 0.10 in the Cr-free spinel. Magnetite activity was calculated using equation (3). The stippled regions refer to type 1 and type 2 spinels, with the former casé including a correction for Cr substitution. Temperature ranges (shown on the abscissa) are taken from the literature²³. The lined region is the f_{O_2} -T range for the San Carlos basanites²⁵. Note the more reduced f_{O_2} s for type 1 xenoliths, and the considerable overlap in $f_{\rm O_2}$ of type 2 xenoliths with the San Carlos basanites.

model^{8,31} and published data for orthopyroxene²⁰ and olivine²¹, neglecting the small expansivities and compressibilities of the phases. The effect of Cr substitution in the spinel phase was estimated using published phase equilibrium data^{13,14} and the formalism of Sack¹⁵. This approach suggests a slight lowering (<1 log unit) of $f_{\rm O_2}$ relative to the Cr-free system if the spinel contains 25 mol% ${\rm Cr^{3+}}$ as ${\rm FeCr_2O_4}$. Preliminary ${\rm Fe_3O_4}$ activity experiments on Cr-bearing synthetic spinels confirm that f_{O_2} is not reduced significantly relative to the Cr-free system.

The observed composition and temperature range for natural spinels in spinel therzolites is shown in Fig. 3 (stippled areas), and gives f_{O} , s which range from slightly below QFM to approximately two orders of magnitude more oxidized. The type 1 (Cr-rich) suite is certainly more reduced than the type 2 (Crpoor) suite; however, our estimates for upper-mantle f_{O_2} are all near or above QFM, in general agreement with previous thermobarometric data⁵⁻⁷, and in sharp contrast to the intrinsic data for spinel separates from type 1 xenoliths (Fig. 1)²⁻⁴. Extremely low Fe₃O₄ concentrations $(X_{\text{Fe}_3\text{O}_4} \approx 10^{-4})$ in the spinel phase would be necessary to stabilize spinel-orthopyroxene-olivine assemblages at an f_{O_2} near IW. However, published analyses $^{22-24}$ do not in general report such vanishingly small magnetite contents; most spinels from spinel-lherzolite xenoliths contain $X_{\text{Fe}_{2}O_{4}} \ge 0.01$. The discrepancy between intrinsic and thermobarometric results must be due to errors in some spinel analyses or to carbon interference in some intrinsic measurements; pressure effects on the latter can be discounted^{8,31}. Experiments are now under way to investigate this discrepancy.

Figure 3 also shows the approximate \bar{f}_{O_2} range for the San Carlos basanites²⁵, corrected to the appropriate temperature and 15 kbar pressure²⁶⁻²⁸. Note the general agreement between the $f_{\rm O_2}$ recorded by type 2 xenoliths and that calculated for the San Carlos basanitic magmas, in which examples of both xenolith suites are entrained. The f_{O_2} data support the conclusion of Frey and Prinz²⁵, based on trace-element abundance patterns of xenoliths from San Carlos and elsewhere, and of Menzies²⁹, based on Sr and Nd isotopic abundances of xenoliths relative to their host magmas, that type 2 xenoliths are cognate, and thus genetically related to the basanites which entrain them, although not necessarily of the same generation. We find no evidence to support the suggestion² that partial melting in the Earth's shallow upper mantle results in a melt-residua system with an f_{O_2} near the IW buffer. This eliminates the need for extensive H_2 loss during magma ascent to explain the observed f_{O_2} s at or above QFM for alkaline and basaltic extrusives⁷.

Our results show that the f_{O_2} accompanying upper mantle processes is not uniform, and may vary from slightly below to approximately two orders of magnitude more oxidized than OFM at 15 kbar total pressure. Our data do not preclude the possibility that low- f_{O_2} zones occur at greater depth or that the mantle was more reduced in Archaean times than at present³⁰. In the spinel-lherzolite facies, however, f_{O_2} s are close to QFM and gaseous species are dominated by CO₂ and H₂O (refs 9, 10), rather than CH₄ and H₂.

We thank Dr Ian Carmichael for performing the wet chemical analyses of our synthetic spinels, and Dr R. J. Arculus for helpful comments on the manuscript. This research was supported by NSF grants EAR-821502 and EAR-8409666.

Crustal detachment during South Atlantic rifting and formation of Tucano-Gabon basin system

Naomi Ussami, Garry D. Karner & Martin H. P. Bott

Department of Geological Sciences, University of Durham, South Road, Durham DH1 3LE, UK

A series of major sedimentary basins of Mesozoic to Tertiary age are associated with the Brazilian continental margin between 8° and 14° S (Fig. 1). This passive continental margin formed when Africa and South America split apart with the initiation of seafloor spreading in the Aptian/Albian3. The offshore basins which border the continental margins on both sides of the Atlantic show evidence of both rifting and crustal attenuation before break-up and thermal subsidence after it. In contrast, a combined stratigraphical and gravity study of the Brazilian onshore basins, which are separated from the offshore basins by a northward-widening strip of Precambrian, suggests that up to 7 km of non-marine sediments were deposited during the rifting stage of the South Atlantic, with no apparent extension of the lower crust beneath these basins and no subsequent thermal subsidence. A mechanism for the linked development of these onshore and offshore basins is proposed here along the lines suggested by Wernicke^{4,5}, in which upper crustal extension in the onshore region is connected to, and balanced against, deeper lithospheric extension beneath the incipient passive margin by intracrustal detachments.

As shown in Fig. 1, the basins adjacent to the Brazilian margin are the coastal Sergipe-Alagoas Basin, and the less well known

offshore Jacuipe Basin which initially adjoined the complementary Gabon Basin on the opposite continental margin. The Brazilian onshore basins extend northward from Reconcavo and include the Tucano and Jatobá 'aborted rift' basins⁶. These are separated from the coast by a triangular Precambrian block.

The Bouguer anomaly map (Fig. 2a) of this section of the Brazilian coast shows that all the basins are characterized by large-amplitude local negative gravity anomalies, indicating thick, low-density sediment infills. The maximum thickness of 7-8 km of sediments in the Tucano Basin produces a local gravity effect of -100 mgal amplitude. Gravity modelling of the Tucano Basin, using sediment densities obtained from density logs of commercial wells, suggests that the observed sediments adequately account for the observed gravity anomaly (Fig. 2b). There is no indication from flanking positive anomalies of significant upwarping of the underlying Moho immediately beneath the basin. In contrast, modelling of the Jacuipe Basin, which has a maximum sediment thickness of $\sim 3-4$ km (ref. 8), suggests that considerable crustal thinning and Moho upwarp has occurred beneath this offshore basin (Fig. 2b).

The Tucano Basin thus gives no evidence of local isostatic compensation, suggesting that it has been formed by uppercrustal extension without complementary extension of the underlying rigid lower crust and uppermost mantle. The lack of local Moho topography as determined by the gravity studies suggests that the lithosphere had a large flexural rigidity at the time of basin formation, and that it has remained high since. Assuming that lithospheric flexure can be modelled as a thin elastic plate overlying a weak fluid substratum, an effective elastic plate thickness of 50-80 km produces a compensating gravity effect of only 10 mgal associated with a regional Moho uplift of ~2 km with a wavelength of 1,000 km (Fig. 2c). This

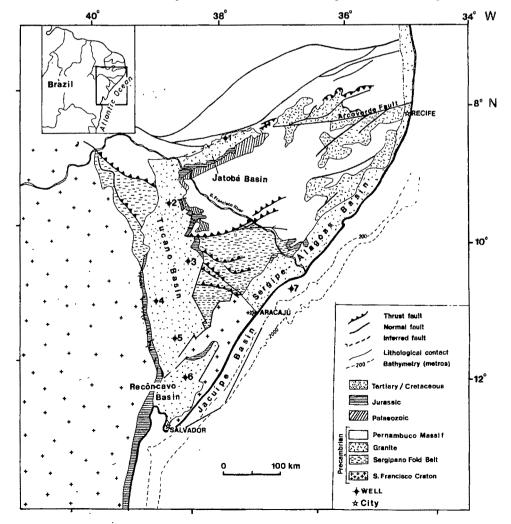

Fig. 1 Geological map of northeastern Brazil (conical projection), modified from ref. 1 to show the Mesozoic to Tertiary sedimentary basins. The onshore Jatobá, Tucano and Recôncavo basins cut across the NW-SE-trending Sergipano fold belt, which extends into Gabon and Angola as the Ndjolé Series². 1-7, Location of wells used in this study.

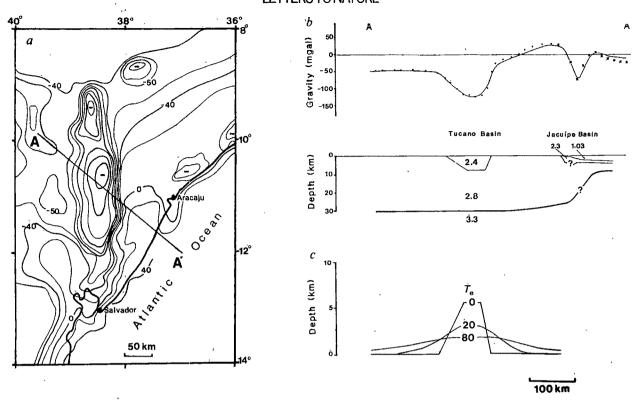

Fig. 2 a, Bouguer anomaly map of northeastern Brazil approximately coinciding with Fig. 1, using Bouguer density of 2.67 g cm⁻³ and referenced to IG\$N71. Contour interval is 20 mgal. Source: Petrobras and DNPM/Brazil. b, Interpretation of a gravity anomaly profile across the Tucano and Jacuípe basins (A-A' in a), based on the Bouguer anomalies (points) and free-air marine anomalies (crosses). The curve is the gravity anomaly profile calculated from the crustal model shown below, in which average densities from commercial wells are shown in g cm⁻³. In the absence of deep seismic data, the depth to the Moho beneath the craton has been assumed to be 30 km. c, Upwelling of the Moho produced by the Tucano Basin upper-crustal mass deficiency, plotted as a function of the effective elastic thickness T_e of the lithosphere.

Moho topography consistent with gravity observations suggests T_e is between 50 and 80 km.

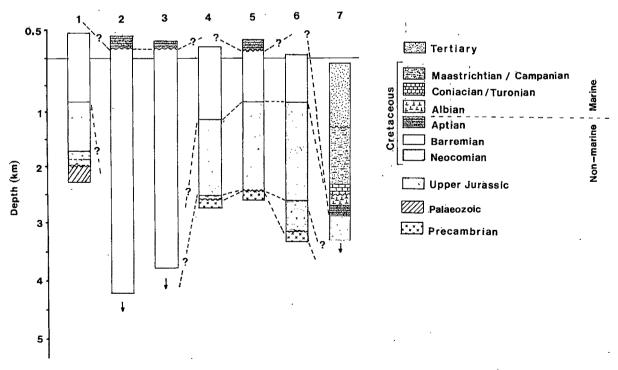

Fig. 3 Simplified stratigraphy of the Jatobá, Tucano, Recôncavo⁹ and Sergipe-Alagoas¹⁰ basins, based on well data provided by Petrobras (Fig. 1). The Upper Jurassic and Neocomian in all basins consist of non-marine shales and sandstones with intercalations of arkose and siltstone. Non-marine sandstones and siltstones of great thickness dominate the onshore basins in the Barremian, and post-rift marine sediments are found only in the Sergipe-Alagoas Basin (well 7).

long-wavelength gravity effect would contribute to the regional anomaly, and the local basin would appear to be uncompensated. Furthermore, the existence of a large rigidity at the time of basin formation implies that the rifting responsible for the Tucano and Jatobá basins was not associated with any significant modification of the thermal structure of the lithosphere immediately below.

Although gravity is useful in defining the present structure of the basins and their isostatic state, it cannot describe their temporal development. However, the stratigraphic evidence obtained mainly from deep wells in the basins is potentially a sensitive indicator of the history of basin subsidence, and thus a further pointer towards the mechanism of formation.

Figure 3 shows the subsidence history and stratigraphy of the Recôncavo, Tucano, Jatobá9 and Sergipe-Alagoas10 basins. Rift subsidence affected all the basins during the period from Upper Jurassic to Neocomian. A total of 5 and 7 km of non-marine Upper Jurassic to Barremian rift sediments were deposited in the onshore Jatobá and Tucano basins, respectively, over a period of ~24 Myr and there is no evidence of any further significant subsidence. The offshore Sergipe-Alagoas and Gabon^{11,12} basins display 3-4 km of non-marine sediments deposited during the rifting stage. In the Sergipe-Alagoas Basin, rift sedimentation terminated in the Barremian, when it was at a maximum in the onshore basins. The initiation of thermal subsidence within the Sergipe-Alagoas and Gabon basins was marked by a major Aptian/Albian marine transgression¹³ which was approximately contemporaneous with the onset of seafloor spreading, and coincident with the abrupt termination of sedimentation and subsidence within the onshore basins. Following non-marine rift sedimentation in the Sergipe-Alagoas and Gabon basins. 3-4 km of post-rift marine sediments were deposited in response to the thermal subsidence of the margin. Thus, there is an intimate relationship between the differing tectonic histories of the onshore basins (Recôncavo, Jatobá, Tucano) and offshore basins (Sergipe-Alagoas, Gabon, Jacuípe), and the inception of the Atlantic seafloor spreading. The lack of thermal subsidence in the onshore basins confirms the inference from the gravity anomalies that their extension was confined to the upper crust during rifting.

According to the mechanism of McKenzie¹⁴ for the formation of sedimentary basins by uniform lithospheric extension, and more recent modifications^{15,16}, rapid rift-stage subsidence is followed by much slower thermal subsidence, with a time constant between 50 and 150 Myr. The simple McKenzie model fails to explain this coupled system of offshore and onshore basins

We suggest that all the basins were formed by lithospheric extension during the rifting phase of Atlantic break-up. Upper crustal extension affected both the onshore and offshore basins, but the extension at deeper lithospheric levels, including the lower crust, was concentrated beneath the offshore basins, as evidenced by the degree of thermal subsidence. In order to permit such coupled differential stretching of the lithosphere, the offshore and onshore regions must have been connected by a low-angle crustal detachment surface.

The potential importance of the crustal detachment in controlling basin formation is strengthened by the evolutionary link between onshore and offshore basins. Whereas all of the basins were initiated at the same time, the cessation of rifting terminated onshore basin development at about the same time as the offshore basins entered into the thermal subsidence phase. The detachment has allowed the transfer of extension between the upper crust and the deeper part of the lithosphere during the rifting stage (Fig. 4b). The origin of the onshore Brazilian basins and the Sergipe-Alagoas and Gabon basins conforms to the 'simple shear model' of Wernicke^{4,5}, in which the non-uniform extension of the crust is balanced by lower crustal and subcrustal lithospheric extension across a detachment surface. Figure 4b shows a schematic but balanced cross-section sum-

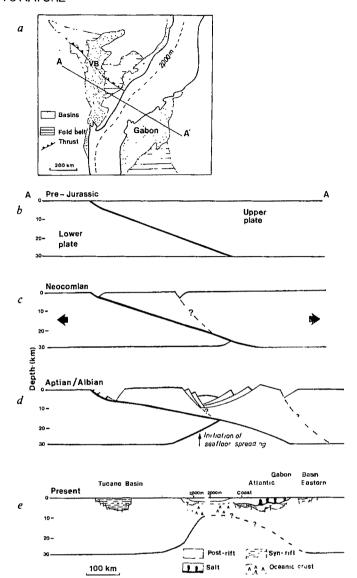

Fig. 4 Suggested history of evolution of the Tucano-Gabon basin system: a, Map showing the line of section (A-A') on a pre-drift reconstruction of Brazil and west Africa; VB, Vaza Barris fault. b, The postulated contact between the African plate (upper plate) and the São Francisco craton (lower plate) is shown as a preexisting thrust fault cutting through the crust and possibly the lower lithosphere, c. Upper Jurassic-Lower Cretaceous extensional regime allows the upper crust to extend and the basal contact to detach, with complementary extension of the lower part of the lithosphere beneath the incipient marginal basins. The collapse of the hanging wall formed the Tucano basin. d, Initiation of seafloor spreading, showing the pronounced thinning of the lithosphere beneath the offshore basins and the asymmetrical position of the split. e, Drifting stage, with thermal subsidence of the offshore basins only. Crustal section based on gravity (Tucano and Jacuípe basins), well¹¹ and seismic data¹² (Gabon Basin). The depth of the Moho under the Gabon Basin is only suggested.

marizing the development history of the Brazilian and African basins using the Wernicke model. The upper plate represents the detached thrust block of the Sergipano fold belt and the African craton; the lower plate represents the Brazilian São Francisco craton.

The Tucano and Recôncavo basins cut across the Upper Proterozoic Sergipano fold belt (Fig. 4a), which extends into Gabon and Angola in western Africa². It is possible that the basal thrust plane of this fold belt has been reactivated as an intracrustal detachment during the Mesozoic extension to form the Jatobá and Tucano basins, while synchronous extension and

rifting was taking place further east, with maximum subsidence affecting the Gabon Basin. The final rupture leading to seafloor spreading took place closer to the present Brazilian margin, where only a small thickness of rift sediments had accumulated in the Jacuípe Basin. The exact break-up position is a complicated function of the changing rheological properties of the extending crust and mantle, the evolving lithospheric temperature structure, and any pre-existing crustal fabric 17,18

In plan view, the upper plate has rotated anticlockwise relative to South America^{19,20}, resulting in the observed distribution of basins around its boundaries. In addition to extension leading to basin formation, complementary compression should be induced along the northeastern border of the block. Such compression may be expressed by the major Harmonia and Itapecuru thrust faults along the northeastern segments of the Arcoverde fault²¹ (Fig. 1).

The formation of the entire Jatobá-Tucano-Gabon basin system in the Lower Cretaceous was controlled by a detachment surface. This detachment allowed the onshore Jatobá and Tucano basins to form by brittle failure of the upper crust in extension, without substantial alteration of the thermal structure of the lithosphere beneath the basins, and it has also acted as a mechanical and temporal link between the onshore basins and the continental margins off Brazil and Africa, thereby allowing balancing of lithospheric extension.

We thank John Dewey and Webster Mohriak for helpful discussions and Petrobras for providing the gravity and well data of the Jatobá and Tucano basins. This work was supported by grants from FAPESP (82/0573-0), CNPq (200348-82), Overseas Research Student Award to N.U. and the Durham University Research Foundation of the Society of Fellows to G.D.K.

Oldest primitive agriculture and vegetational environments in Japan

Matsuo Tsukada, Shinya Sugita & Yorko Tsukada

Quaternary Ecology Laboratory AK-60, Department of Botany, University of Washington, Seattle, Washington 98195, USA

In Japan, shifting agriculture as part of a hunting and gathering strategy was generally thought to have started during the Middle Jomon period (5,000-4,000 BP)¹⁻⁴. We present here evidence of primitive agricultural activities at least 1,600 years earlier than this date. At the Ubuka bog on the coast of the Sea of Japan in southwestern Honshu (34°29' N, 131°35' E, 390 m altitude) buckwheat cultivation dates back to as early as 6,600 BP in the Early Jomon period (7,000-5,000 BP). The warm-temperate climatic regime in that period supported the growth of Podocarpus, Cyclobalanopsis, Ilex crenata/I. serrata and Viscum album var. coloratum. Slash-and-burn agriculture was intensified ~2,000 BP and rice cultivation was introduced ~1,500 BP.

The evidence that slash-and-burn agriculture in the Japanese Archipelago began as part of a generalized subsistence system during the Middle Jomon period is: (1) the abundant occurrence of stone mortars and pestles and chipped stone axes; (2) the establishment of large, permanent villages; and (3) the occurrence of functionally diverse pottery associated with a plant diet1-4. However, there has been no direct evidence of agricultural activities, with the exception of nine Phaseolus aureus legumes and nine Lagenaria leucantha seeds at the Torihama shell mound site³ of the Early Jomon period (Fig. 1).

Fagopyrum esculentum (buckwheat), Setaria italica (foxtail millet), Echinochloa crus-galli var. frumentaceum (Chinese barnyard grass), Panicum miliaceum (Chinese millet) and Oryza sativa (rice) are all native to the Asiatic mainland⁵⁻¹⁰. These crop plants cannot survive in the moist forested landscape of Japan, unless they are protected by humans, and no pollen grains or seeds of these species have been found in Japanese Pleistocene sediments which have been extensively studied. The

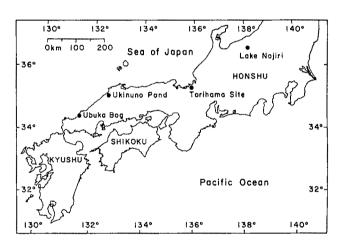

Fig. 1 Index map of sites mentioned in the text.

presence of macroscopic and pollen remains of these plants in Japanese sediments therefore indicates that people were growing them at the time of their deposition¹⁰. Buckwheat, whose pollen can be identified to the species level^{11,12}, is an excellent index species to assess past agricultural activities.

Fossil buckwheat pollen grains were first found in sediments of Lake Nojiri (36°50' N, 138°14' E, 654 m altitude), dated between 1,500 BP and the present¹¹. In these sediments, the pollen of herbaceous taxa, for example Chenopodiaceae and Liguliflorae, and *Pinus densiflora*, a lowland "pioneer" pine species, begin to increase in frequency immediately after the first occurrence of buckwheat pollen, indicating that shifting agriculture intensified ~1,500 years ago^{10,12}. Some species of these herbaceous taxa can become weeds in agricultural and deserted lands.

Since this first discovery, fossil buckwheat pollen grains have been found at various archaeological sites of the Late Jomon period (4,000-3,000 BP)¹³⁻¹⁵ and a single, carbonized fragment of buckwheat seed has been found on a house floor of the Early Jomon period in southern Hokkaido¹⁶. However, archaeological

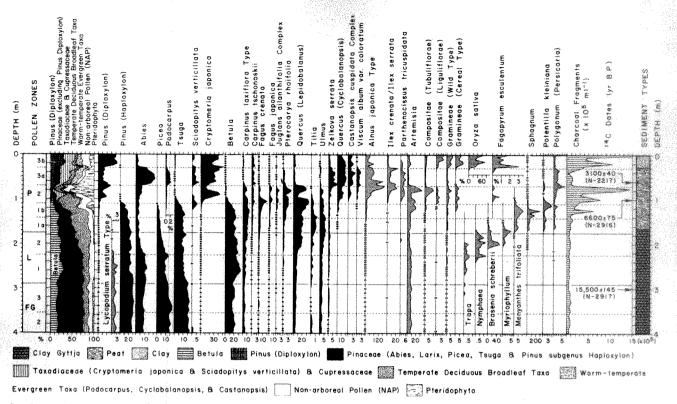

Fig. 2 A pollen diagram of the Ubuka bog, southwestern Japan. Analysis was made at 5-cm intervals from the surface to the 270-cm level, and at 10-cm intervals below the 270-cm level. Percentages are based on the pollen sum (>1,000 grains per level) of upland arboreal taxa, and those listed in the summary diagram (left column) are based on the sum of pollen and spores of terrestrial plants. Dots indicate values of less than 0.2% for Lycopodium and Tilia, 0.3% for Carpinus latifolia type, Juglans, Pterocarya, Viscum, Compositae (Liguliflorae), Myriophyllum, Potentilla, and Persicaria, 0.5% for Abies, Picea, Tsuga, Zelkova, Menyanthes, and Compositae (Tubliflorae), 1.0% for Pinus, Cryptomeria, Betula, Fagus, Quercus, Carpinus laxiflora type, Gramineae and Ilex, and 5% for Alnus.

sites are often disturbed by past occupations, making it impossible to reconstruct the history of fossil pollen and seeds precisely, and one seed is not a conclusive demonstration that buckwheat cultivation was practised at a particular site. In contrast to this, bog and lake sediments are well stratified and can provide a reliable picture of buckwheat history.

We have now found definitive evidence of primitive agriculture at the Ubuka bog shown in Fig. 1 (1,000 m N-S ×1250 m E-W). During the full- and late-glacial period the basin was a lake, characterized by gyttja sediments with cladoceran remains, but it was gradually obliterated by sediment accumulation between ~13,000 and 8,500 BP. All dates are based on three ¹⁴C datings [3,100±90 BP at 60 cm (Nippon Isotope Association sample number N-2217), 6.600±75 BP at 100 cm (N-2916), and 15,500±175 BP at 300 cm (N-2917)] and the correlation with dated pollen zonal boundaries in southwestern Japan. A well-ordered succession from shallow-lake aquatic plants (Trapa, Nymphaea tetragona, Brasenia schreberii, Myriophyllum and Menyanthes trifoliata) to bog plants (Sphagnum, Potentilla kleiniana and Persicaria) is evidence of this change (Fig. 2).

About 7,700 years ago, or soon after the bog was formed, the forest surrounding the basin was disturbed. This is indicated by a sudden increase in the deposition of charcoal fragments of woody plants at this time. These fragments are large in size but make up only 1.1% of the total (Fig. 3). Grass pollen grains found in these strata have not been identified at the species level but many are $>41~\mu m$ (Fig. 2), suggesting that cereal plants $^{17-20}$ may have been under cultivation in the Early Jomon period. No grass pollen $>35~\mu m$ occurred in sediments accumulated before $\sim 7,500~\rm Bp$.

The deposition of charcoal fragments increased further $\sim 6,600$ BP. Some of these fragments are 150-400 μm (Fig. 3), indicating that forest fires occurred nearby. Buckwheat pollen

grains were found in abundance $(75.8 \pm 61.7 \text{ cm}^{-3})$ in sediments dated $\sim 6,600-4,500 \text{ BP}$. Herbaceous 'pioneers', for example Artemisia and other Compositae, are also conspicuous during this period and pine (mostly *P. densiflora*) reaches a frequency of 28% total pollen. It is unlikely that buckwheat was cultivated on the Ubuka bog at this time because no peat disturbance was observed and Alnus japonica and Ilex crenata/I. serrata actively invaded the bog during this period (Fig. 2).

Even after a considerable search of the Ubuka sediments. neither buckwheat nor cereal pollen were found in the sediments deposited between ~4,500-2,000 BP, approximately corresponding to pollen zone P-3a time21 (Fig. 2), probably because agricultural activities were moved to sites at a distance from the bog. Temperate conifers (Abies firma and Cryptomeria japonica) increased in frequency immediately after agricultural activities ceased. Carbon fragments became smaller and the Kolmogorov-Smirnov two-sample test²² shows that, at the 0.01 significance level, their frequency curve is identical to those of distant fires recorded at the 230-cm level (~12,400 BP) and other late- and full-glacial levels not shown in Fig. 3. Heavy charcoal and buckwheat pollen should have not been carried from the distant sites to the bog during the P-3a zone. However, a relatively high frequency of Diploxylon pine pollen during this period indicates that human groups still continued to disturb the forests distant from the bog (Fig. 2).

The primitive agricultural activities approximately correspond to the Japanese Hypsithermal interval, or pollen zone P-2 time $(7,000-4,000 \text{ BP})^{21,23}$. By $\sim 7,000 \text{ BP}$, populations of many cool-temperate species, for example spruce (*Picea*), basswood (*Tilia*) and birch (*Betula*), declined in frequency or disappeared completely from the Ubuka area. A rapid decline of beech (*Fagus*) and oak (*Quercus*) pollen $\sim 6,600 \text{ BP}$ suggests that forest fires may have killed many trees around the Ubuka bog and that

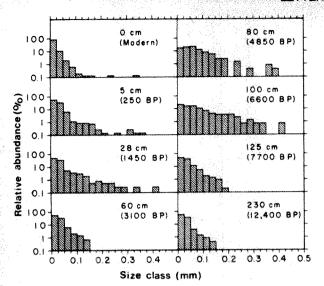

Fig. 3 Frequency curves of charcoal fragments at selected levels of the Ubuka core. N (total number fragments counted) = 224 at level 230 cm; 621 at 125 cm; 261 at 100 cm; 245 at 80 cm; 294 at 60 cm; 357 at 28 cm; 797 at 5 cm; 1,593 at 0 cm. Approximate dates, calculated from three radiocarbon dates (Fig. 2) and dated pollen zonal boundaries^{21,28}, are given in brackets.

after these disturbances Pteridophyta (which includes bracken) characterized the Early Jomon landscape. Also common were warm-temperate species such as Podocarpus (which can grow in areas above the 2 °C January isotherm24) and Cyclobalanopsis (cyclic cup oak, a subgenus of Quercus).

Cryptomeria japonica, a temperate moisture-loving species which requires at least 1,600 mm of annual precipitation^{25,26} began to increase at the beginning of pollen zone P-2 time. Both this species and Sciadopitys verticillata declined temporarily ~5,000-4,000 BP as a result of forest disturbances. Ilex pollen is unusually high (6-20% of total tree pollen) during this period. Pollen of this entomorphilous genus would not be found in such abundance unless the swamp species, either Ilex crenata, I. serrata, or both, had invaded the bog 7,000 BP. A more important finding is that Japanese mistletoe (Viscum album var. coloratum) arrived at this area ~7,500 BP and has continued to grow up to the present day. Although the climatic factors under which this species can grow and reproduce sexually have not been studied (as has been done for the European species²⁷), its presence together with Podocarpus suggests a warm winter climate.

About 2,000 years ago, buckwheat was again cultivated near the bog; people have continued to grow it here until the present day. The buckwheat pollen frequency for the past 2,000 years is much higher than that observed during the first period of cultivation. Large charcoal fragments are also observed at all analytical levels deposited during this period. The fragments $>150 \mu m$ are 16.9% at level 100 cm (\sim 6,600 BP), 9.4% at 80 cm (4,850 BP), 3.6% at 28 cm (1,450 BP), 1.8% at 5 cm (250 BP) and 0.4% at 0 cm (Fig. 3). The frequency for the upper levels is low because small charcoal fragments were carried from distant agricultural areas to the bog and further fragmented by farming activities on the paddy field. These facts suggest that much more intensified slash-and-burn agriculture has been practised in the area for the past 2,000 years.

Although the clay sediments above the 28-cm level were disturbed by rice cultivation on the bog, pollen succession of upland plants here is almost identical to that established at the nearby Ukinuno Pond site28 about 127 km northeast of Ubuka (Fig. 1). At Ubuka, however, buckwheat pollen was found in an undisturbed peat layer, indicating that intensified shifting agriculture began slightly before the disturbance of the bog caused by wetland rice cultivation. By interpolating the sedimentation rate between the modern level and the level radiocarbon-dated at 3,100 ± 90 yrs, the date of the first rice pollen can be estimated at about 1,500 BP. This is within the period when rice agricultural practice was intensified along the coast of the Sea of Japan in southwestern and central Honshu²⁸.

These intensified agricultural activities almost completely

destroyed the temperate Abies and Cryptomeria forests at the Ubuka area. Red pine increased further and currently comprises ~40% of total tree pollen. Among the herbaceous pollen, an increase of Liguliflorae is also conspicuous; its abundance level is higher than that observed during the earlier agricultural episode. Since rice cultivation was practised on the bog, plants such as Ilex and Alnus have sharply declined in abundance

The presence of fossil buckwheat pollen grains and the sudden increase of charcoal fragments at the Ubuka basin ~6,600 radiocarbon years ago provide evidence of agricultural activities in Japan at least 1,600 years earlier than the previously inferred date. Buckwheat was introduced from central China, which is considered to be the probable centre of buckwheat cultivation⁵⁻⁹. The coast of the Sea of Japan in southwestern Japan, directly facing mainland Asia, is a likely place for shifting agriculture to have begun. Further extensive studies along this line, with detailed pollen and charcoal analyses, are needed to clarify the existence of earlier agriculture and its migration routes both in East Asia and within the Japanese Archipelago.

The guanine nucleotide-binding stimulatory protein (G,) couples hormone-receptor interaction to the activation of adenylate cyclase and the generation of cyclic AMP (see ref. 1 for a review). Studies using frog neuroepithelium indicate that the sense of smell is mediated by a G,-adenylate cyclase system2, and this prompted us to test olfaction in the only known model of G, deficiency in the animal kingdom, G_s-deficient (type 1a) pseudohypo-parathyroidism (PHP), which occurs in humans³⁻⁸. Such patients are resistant to the cAMP-mediated actions of several hormones9. (Although Henkin10 has reported disturbances in the sense of smell in six patients with PHP, currently available biochemical measurements such as the cAMP response to parathyroid hormone (PTH) and determination of G, activity were not reported and olfactory

testing was limited.) In the present study, we found that all Gsdeficient patients had impaired olfaction when compared with PHP patients who had normal G, activity (type 1b PHP, in which patients are resistant only to the action of PTH in the kidney). This is the first evidence of human olfactory impairment which can be related to G. deficiency and suggests that G.-deficient PHP patients may be resistant to cAMP-mediated actions in other non-endocrine systems.

We tested olfaction in five patients with type 1a PHP, who typically express variable resistance to the cAMP-mediated actions of several hormones^{3,9,11-13} and in seven patients with type 1b PHP, who are not resistant to the action of other hormones whose activities are mediated via cAMP9. Informed consent was obtained. The diagnosis of PHP was based on the information shown in Table 1. All PHP patients had hypocalcaemia with elevated PTH levels at the time of diagnosis, normal renal function, and all required therapy with calcium and vitamin D. Nine of the 12 patients were infused with 250 U of parathyroid extract and had markedly impaired urinary cAMP responses. All five type 1a PHP patients had deficient erythrocyte G_s activity and features of Albright's osteodystrophy. All were resistant to thyroid stimulating hormone (TSH) with elevated basal or thyrotropin releasing hormone-stimulated TSH levels, and all require treatment with thyroid hormone (Ta) for hypothyroidism. These five patients all had negative titres of anti-thyroid antibodies, suggesting that such patients are demonstrating thyroid resistance to TSH for reasons other than autoimmune thyroid disease. At the time of olfaction testing, all PHP patients were being treated with calcium and vitamin D and all the type 1a patients were also receiving supplements of thyroid hormone. This is important because several endocrine deficiencies, including hypothyroidism, have been reported to be associated with olfactory dysfunction¹⁴. Serum calcium, phosphorus,

Erythrocyte G_s activity was determined as previously reported^{5,8}. Blood was anticoagulated with acid citrate dextrose and erythrocyte membranes were prepared within 48 h of collection. Erythrocyte membranes were prepared by hypotonic lysis in 5 mM sodium phosphate (pH 8.0) at 0 °C and stored at -70 °C. G. activity was extracted from erythrocyte membranes in detergent and assayed by addition to CYC membranes. Membranes from the CYC clone (94-15-1) of \$49 mouse lymphoma cells, genetically deficient in G_s activity ¹⁶, were prepared as described previously ¹⁷. Erythrocyte membrane pellets were prepared by centrifugation and solubilized in buffer A (2.0 mg protein ml -1, 10 mM Tris-HCl pH 7.5, 10 mM MgCl₂, 0.1 mM EDTA, 1 mM dithiotreitol, 0.2% (w/v) Lubrol PX) and incubated at 4 °C for 60 min with frequent vortexing. The membrane suspensions were then centrifuged for 3 min at 50,000g and the supernatant solutions (membrane extract) collected and retained at 0-4 °C for immediate assay of G, activity. CYC membranes (200 µg) and soluble erythrocyte membranes (10 µg) were incubated for 20 min at 30 °C in 80 µl of buffer B containing 30 mM Tris-HCl (pH 7.5), 10 mM MgCl₂, 1 mM dithiothreitol, 20 µM cAMP, 5 mM creatine phosphate, 3.3 IU of creatine phosphokinase, 100 µM ATP, isoprenaline (10 µM) and guanosine 5'-O-(3-thiotriphosphate (GTP-y-S; 100 µM). After the 20-min incubation, 20 µl of buffer B containing [a⁻²³P]ATP (0.1 Ci mmol⁻¹) was added and incubation continued for a further 20 min at 30 °C. cAMP was isolated and determined by the method of Salomon et al. Expitrocyte extracts alone did not show measurable adenylate cyclase activity. Adenylate cyclase activity of CYC membranes in response to isoprenaline/GTP-y-8 (1.0-1.5 pmol cAMP per tube) was subtracted from the activity of combined erythrocyte extract and CYC membranes to obtain the increment due to addition of erythrocyte G activity. Results of assays are expressed in relation to the activity of a standard membrane preparation consisting of pooled erythrocytes from four normal persons and represent the mean of three determinations. ND, not done.

Values obtained when the patient was receiving treatment with calcium and vitamin D.

† Serum PTH determinations were performed by four different research or reference laboratories. ‡ Plasma cAMP=25 pmol ml⁻¹ (normal > 150).

All G_s-deficient patients were receiving therapy with calcium, vitamin D and thyroid hormone. All PHP patients with normal G_s activity were receiving therapy with calcium and vitamin D.

Anti-thyroid antibodies present.

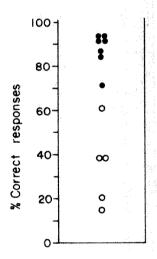

Fig. 1 Results of olfaction testing in patients with type 1a PHP (open circles) and patients with type 1b PHP (closed circles). Methods. Each patient was evaluated by asking them to identify repeatedly 10 common odorants presented at concentrations found to be representative of their counterparts in nature, which frequently are odorant mixtures rather than single pure chemicals: 3.6015 M ammonia (ammonia), 0.0622 M trans-cinnamaldehyde (cinnamon), 0.0130 M anethole (licorice), 0.3990 L-carvone (mint), 0.0244 M napthalene (mothballs), 0.0121 M D-limonene (orange), 1.0467 M phenethyl alcohol (rose), 0.7425 M isopropyl alcohol (rubbing alcohol), 0.0273 M vanillin (vanilla), and 4.3714 M acetic acid (vinegar)15. The diluent was odourless propylene glycol. The odorants were successively presented with the sniff-bottle technique randomly for each subject in blocks of 10, with the constraint that when moving continuously from one block to the next, no one odorant followed itself. The subjects were informed of the odorants which were to be presented and could use any sniffing strategy they desired, but were encouraged to make their identification decision after about two sniffs. It has been shown that a single natural sniff is usually sufficient for optimum odorant perception, and that additional sniffs are probably only confirmatory¹⁹. The results are expressed as the percentage of 100 odorant presenta-

T4. TSH and PTH values at the time of testing are shown in Table 2. No patients had upper respiratory infections or other active nasal problems that could influence their sense of smell.

Olfaction was evaluated by a quantitative test which required patients to identify 10 common odours that were repeatedly presented in a random fashion15. Figure 1 shows the results. All five type 1a PHP patients demonstrated impaired olfaction compared with the seven type 1b PHP patients. One of the latter group had quantitative olfactory dysfunction when compared with normal subjects, but even this patient scored much better on olfactory testing than any of the type la patients.

Levine, M. A. et al. Am. J. Med. 74, 545-556 (1983).

Our study shows that G, deficiency is associated with decreased olfactory ability and provides the first evidence of a mechanism involving G_s-adenylate cyclase in human olfaction. It further demonstrates that PHP, a disease traditionally thought to be characterized by endocrine dysfunction, may involve other organ systems in which specific effects are mediated via cAMP.

tions (10 for each odorant) identified correctly

Synthesis of fast myosin induced by fast ectopic innervation of rat soleus muscle is restricted to the ectopic endplate region

G. Salviati*†, E. Biasia† & M. Aloisi†

* Centro di Studio per la Biologia e Fisiopatologia Muscolare del CNR and † Istituto di Patologia Generale dell'Universita' di Padova, via Loredan 16, 35131 Padova, Italy

Skeletal muscle fibres, long multinucleated cells, arise by fusion of mononucleated myoblasts to form a myotube that matures into the adult fibre. The two major types of mature fibre, fast and slow fibres, differ physiologically in their rate of isotonic shortening1. At the molecular level these type-specific physiological properties are ascribed to different isoforms of myosin, a major protein involved in shortening^{2,3}. Differentiation of fast and slow fibres seems to be under the control of motoneurones4, and mature fibres are innervated by only one motoneurone. When rat soleus muscle (SOL, a slow muscle) is dually innervated with a fast nerve, it acquires some properties of a fast muscle, that is, low sensitivity to caffeine and high glycogen content5. We report here that in dually innervated soleus muscle the foreign fast nerve induces synthesis of fast isoforms of myosin, but only in the segment of the muscle fibre that is close to the foreign endplate. The localized influence of the nerve endplates suggest that factors controlling the phenotypic expression of the muscle fibre have a short range

The nerve of the fast extensor digitorum longus (EDL) muscle of male Wistar rats (each weighing 160 g) was transposed and inserted with the aid of a glass capillary under the fascia of the soleus muscle, in the proximal third of the muscle. Care was taken not to damage the muscle fibres underneath. After 3 weeks, the SOL was temporarily denervated by crushing and freezing its motor nerve with clamps that had been immersed in liquid nitrogen. This procedure enables the soleus muscle fibres to be innervated rapidly (as early as 3 days after nerve crushing⁶) by the fast nerve, which forms new endplates that are functionally normal and remain active for long periods, perhaps indefinitely Also, after 2 weeks the normal nerve re-establishes contacts with the target fibres at the orginal neuromuscular junctions7. We studied the dually innervated SOL either 3 or 14 months after surgery, electrically stimulating the muscles via the nerve to be certain that both normal and foreign nerves could induce contraction. All operated muscles (n = 10) contracted on stimulation of either nerve. We dissected the operated soleus muscle, and, as a control, the contralateral muscle, and mounted them on a wooden stick, then chemically skinned the fibres to extract soluble sarcoplasmic proteins that would interfere with the identification of myosin light chains and regulatory proteins in the gels8.

To identify dually innervated fibres, we treated bundles of muscle fibres with a skinning solution (170 mM K-propionate, 2.5 mM Mg propionate, 2.5 mM ATP, 5 mM EGTA, 10 mM imidazole-propionate, pH 7.0) containing bungarotoxin labelled with fluorescein isothiocyanate, a reagent that binds to the acetylcholine receptors. In both control and experimental muscle fibres, a-bungarotoxin was localized exclusively at the endplates. We dissected single fibres and examined them by fluorescence microscopy to identify those with two endplates. These were found in the proximal end (1-2 mm from tendon insertion, ectopic endplate) and in the middle region of the muscle fibre (5-6 mm from the ectopic endplate) where endplates are normally localized. We solubilized fibres in SDS-containing solution and analysed myofibrillar protein isoforms by SDS-gel electrophoresis on a discontinuous

Single muscle fibres, showing two separate endplates after abungarotoxin labelling, were isolated from 3-months (4 muscles) or 14-months (6 muscles) operated soleus muscles. Each fibre was cut into four segments (each 2 mm long starting from the proximal end). Fast (F) and slow (S) myosin heavy chains were separated by 5% SDS-gel electrophoresis and stained with silver. (+) indicates the amount of fast and slow MHC in each fibre segment. Fibre segments were 2 mm long.

system9 as described previously8,10.

The presence of two separate endplates in the same fibre may not be an absolute criterion for dual (fast and slow) innervation. It has been reported that in some instances branches of the same foreign motor nerve form separated endplates on the same muscle fibre when the original nerve was cut and prevented from reinnervating the muscle¹¹. Furthermore, many denervated

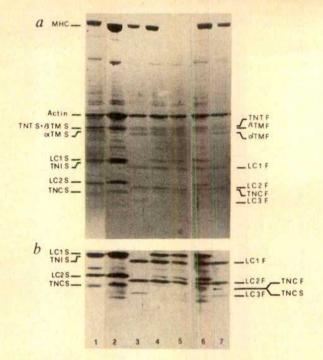

Fig. 1 Pattern of myofibrillar proteins of single fibres from operated soleus muscle. SDS-gel electrophoresis on 10-20% polyacrylamide linear gradient of chemically skinned single-fibre proteins. Lanes 1, 2, control slow fibres from SOL muscle; 3, 7, control fast fibres from EDL muscle; 4-6, dually-innervated soleus fibres identified by fluorescent α-bungarotoxin labelling (see text). In lane 5, MHC material is missing because of a cracking in the gel. After electrophoresis the gel was stained with Coomassie Brilliant Blue (panel a), destained and stained with silver (panel b); in b only the region of MLC is shown. F, fast; S, slow; MHC, myosin heavy chain; LC, myosin light chain; TNT, TNI, TNC, troponin T, I or C; TM, tropomyosin.

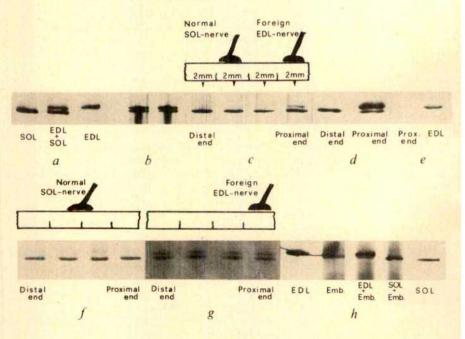

endplates of muscle cross-innervated by a foreign nerve at a distant location continue to bind normal amounts of α -bungarotoxin for more than 4 months¹². However, at later stages (30-40 weeks) after denervation of the original nerve, a decreased acetylcholine sensitivity has been demonstrated in non-reinnervated original endplates⁷. Most of our fibres were analysed 14 months after the operation and no differences were found in the intensity of α -bungarotoxin fluorescence between ectopic and original endplates. This result and the fact that operated soleus muscles contracted to electrical stimulation of either normal or foreign nerve suggest, although do not prove, that most of the original endplates were reinnervated by the normal nerve⁷. The possibility still exists that not all the fibres studied were in fact dually innervated.

Fast and slow myosin light chains (MLC), tropomyosin (TM) and troponin (TN) showed different apparent relative molecular mass (Fig. 1; lanes 3, 7 and 1, 2, respectively). Fourteen months after surgery, all experimental soleus fibres (n = 13) contained

both fast and slow isoforms of MLC, TM and TN (Fig. 1; lanes 4-6), indicating that the foreign fast nerve could activate synthesis of fast isoforms of MLC and the regulatory proteins. Fast and slow rat myosin heavy chains (MHC) can be identified by an electrophoretic gel system that requires very little protein (ref. 13; Fig. 2a), making it possible to study the composition of MHC in single fibres. In all experimental fibres (n = 13), we found both fast and slow MHC (Fig. 2b), although the relative proportion of the two isomyosins varied. Furthermore, the additional protein band which appeared in experimental fibres was selectively immunostained by a monoclonal antibody specific for adult fast MHC (Fig. 2e). These findings indicate that a fast nerve implanted onto a normally innervated slow fibre modify the 'trophic' effect of the slow nerve, activating genes encoding fast myosin.

Our results, however, raise another question: whether the effect of the fast nerve was exerted on the entire fibre or only near the fast endplate. To answer this question, we cut experi-

Fig. 2 Expression of fast myosin heavy chains by single fibres from operated soleus muscle. MHC (~50 ng protein) were separated by SDSgel electrophoresis on 5% polyacrylamide gel and stained with silver, a. Control muscles: b. total protein of two dually innervated fibres (see Fig. 1); c, dually innervated fibre 3 months after surgery-4 fibre segments of the same length (2 mm) were cut as shown by the upper scheme and separately electrophoresed; d, dually innervated fibre 14 months after surgery-the fibre was cut into two halves about 4 mm long, that were separately electrophoresed; e, dually innervated fibre cut as in d and EDL control fibre after blotting²³ and immunostaining with anti-rat fast MHC monoclonal antibody (24D5); f, contralateral, control, soleus muscle fibre-four segments (2 mm long) were cut and processed as c; g, fibre (10 mm long) from 14months operated soleus. This fibre, after fluorescent a-bungarotoxin labelling, showed only the foreign endplate at the proximal end-MHC were analysed in four segments as shown in c; h, rat embryonic MHC does not co-migrate with adult fast and slow MHC. Embryonic myosin was purified from 12 days rat fetus hind limb muscles according to ref. 24.

mental fibres into four segments (2 mm long) from the proximal end, where the fast endplate was located. Although fast MHC are found in all fibres 3 or 14 months after surgery (Fig. 2C-D; Table 1), they are detected almost exclusively in the segment of fibre that bears the fast endplate and no fast MHC is ever detected in the segment containing the slow endplate or that located more distally. Only the proximal segment of six 14month dually innervated fibres is stained by histochemical myofibrillar ATPase reaction, after precincubation at pH 10.4, that is, after inhibition of slow myosin ATPase activity (data not shown). Normal soleus fibres contained only slow MHC, even in the segment corresponding to the proximal end (Fig. 2f). By contrast, a fibre from a single 14-month operated soleus muscle, in which only the foreign endplate at the proximal end was demonstrated by the α -bungarotoxin labelling, contained both fast and slow MHC, but the relative amounts of the two isoforms were constant throughout the entire fibre length (Fig. 2g).

We conclude that this fibre is a slow fibre 'cross-innervated' by the fast nerve that undergoes a partial slow-to-fast transformation, in agreement with previous results14. The possibility that the additional band seen in experimental fibres could have been contributed by synthesis of embryonic myosin induced by denervation was excluded because the heavy chains of purified rat embryonic myosin show an electrophoretic mobility intermediate between those of heavy chains of adult fast and slow myosin, and closer to that of slow MHC (Fig. 2, lane 4) and, therefore, it cannot co-migrate with the additional band. These findings demonstrate that the phenotypic expression of myosin isoforms may differ along the length of these single muscle fibres and suggest that this localization is related to the presence of a specific neural input. Clearly this trophic influence may only be exerted over a rather short distance from the endplate.

It is not known what is the message transmitted from nerve to muscle, nor which mediators in the muscle cell activate gene expression. Electrical activity may be the main message transmitted by a nerve^{5,16}, but there may be certain chemical factors (trophic factors)^{17,18}, some of which appear to control specific electrical characteristics of the muscle surface membrane¹⁹. The pattern of electrical activity seems important because the trains of action potentials propagate all along the fibre and could induce formation of mediators that control in a coordinated manner the activation of either 'fast' or 'slow' genes in all nuclei of the fibre. Moreover, direct stimulation by short highfrequency bursts of impulses (fast pattern of stimulation) is more effective than more prolonged trains of low-frequency impulses (slow pattern) in restoring normal membrane properties after denervation²⁰. But the pattern of electrical activity cannot fully explain why the expression of fast genes is restricted to the region around the endplate.

Nonetheless, the localized synthesis of fast myosin in a slow fibre indicates that only a few nuclei are affected by the fast endplate, and that specific chemical mediators must be formed in the muscle cell, but near the endplate. A preferential localization of a muscle membrane antigen (5.1.H11) near the nucleus responsible for its production has been reported in muscle heterokaryons in vitro²¹. On the other hand, 'mosaic' skeletal muscle fibres from mouse chimaeras show no spatial phenotypic heterogeneity related to genotypically distinct myonuclei2 These findings are not inconsistent with our results, because in mosaic fibres genotypically distinct myonuclei are randomly distributed, whereas in our experimental model it is the cytoplasmic mediator(s) which have a limited range of activity.

We thank Professor F. Clementi (Department of Pharmacology, University of Milan) for the gift of fluorescein isothiocyanate-labelled α -bungarotoxin; Professor S. Schiaffino for the monoclonal antibody; and Dr D. Parry for help in the immunostaining experiment and a critical review of the manuscript. We also thank Drs I. Mussini and V. Benvenuti for design of surgical procedures, and Drs L. P. Rowland, S. Di Mauro

and A. Miranda (Department of Neurology, Columbia University, New York) for helpful discussion. Supported by institutional funds from the Consiglio Nazionale delle Ricerche and by a grant from the Ministero della Pubblica Istruzione.

The tight junction does not allow lipid molecules to diffuse from one epithelial cell to the next

Gerrit van Meer, Barry Gumbiner* & Kai Simons

European Molecular Biology Laboratory, Postfach 10.2209, D-6900 Heidelberg, FRG

The tight junction (zonula occludens) links epithelial cells into a monolayer by forming a continuous belt of sealing contacts around the apex of each cell. They appear in thin sections as if they were 'fusions' between the apposed plasma membranes' and in freezefracture replicas as patterns of complementary strands and furrows2. These images have led to the proposal that the core of the tight junction is formed by a hexagonal cylinder of lipids^{3,4}. In this model, the cytoplasmic leaflet of the apical and basolateral plasma membrane domains would be continuous, whereas the exoplasmic leaflets of the two plasma membrane domains of the same cell would be separated at the tight junction and are instead predicted to be continuous between the plasma membranes of neighbouring cells. We demonstrate here that this prediction does not hold true. An endogenous glycolipid (Forssman antigen), present in the exoplasmic leaflet of the apical membrane of MDCK strain II cells 5,6, is unable to pass to MDCK strain I cells (which lack this glycolipid) under conditions where these cells are connected by tight junctions. In addition, fluorescent lipids which have been fused into the plasma membrane^{7,8} of one MDCK cell do not diffuse to neighbouring cells while the tight junctions between the cells are intact.

To test whether lipids can diffuse from one epithelial cell to another through continuous exoplasmic leaflets of their apical plasma membranes, we studied the behaviour of endogenous glycolipids. Strain II MDCK cells, a subline of the MDCK cell line9, possess a series of glycolipids, the globo series, which are not found in MDCK strain I cells, a different MDCK subline "" Forssman antigen, one glycolipid of this series [GalNAc(α)-3)GalNAc(β 1-3)Gal(α 1-4)Gal(β 1-4)Glc(β 1-1)Cer], constitutes 21% of the total neutral glycosphingolipids of MDCK strain II cells⁵. When a monolayer of these cells was labelled

Present address: Department of Pharmacology, School of Medicine, University of California

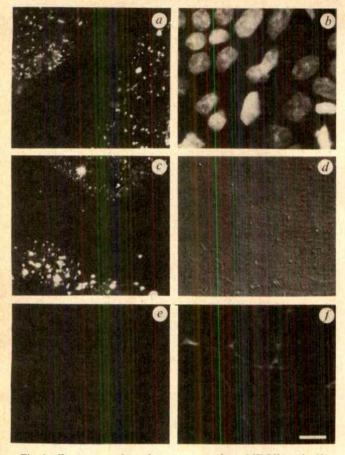

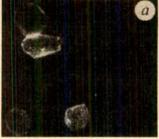

Fig. 1 Forssman antigen does not move from MDCK strain II cells to MDCK strain I cells during 96 h of co-culture. a, A mixed monolayer of MDCK strain I and strain II cells on nitrocellulose filters was fixed with 3% formaldehyde and incubated on the apical surface with monoclonal IgGs against Forssman antigen. Clustering of the fluorescent anti-Forssman antibodies in Fig. 1a is prevented if unfixed cells are incubated with the antibody at 0 °C and postfixed before addition of the second antibody (C. M. B. Butor and J. Davoust, unpublished results). As a second antibody we used rhodamine anti-mouse IgG. b, The same field of cells after staining the DNA in the nuclei by Hoechst dye 33258. c, A mixed monolayer grown on a glass coverslip stained apically against Forssman antigen as described for a. d, Nomarski optics micrograph of the field shown in c. e, Parallel monolayers on coverslips were incubated on the apical surface with a monoclonal antibody against uvomorulin, a lateral membrane marker in these cells1 As a second antibody we used rhodamine anti-mouse IgG. f. Staining with the anti-uvomorulin antibody after opening of the junctions by incubation with 2 mM EGTA for 5 min at 37 °C (ref. 10). Scale bar, 10 µm.

from the apical side with a monoclonal antibody against Forssman antigen, apical staining was observed (see also Fig. 4 of ref. 5). This glycolipid was therefore present in the exoplasmic leaflet of the apical plasma membrane. We co-cultured MDCK strain II cells with MDCK strain I cells which do not express Forssman antigen. The presence of intact tight junctions between the two cell types was demonstrated by adding a monoclonal antibody which recognizes uvomorulin, a protein present on the lateral membrane of MDCK cells10, and showing that it did not label the lateral membrane unless the tight junctions had been opened by treatment with 2 mM EGTA for 5 min at 37 °C before fixation (Fig. 1). Therefore, tight junctions were present between strain I and II cells grown together on nitrocellulose filters or glass slides. Staining with 33B12, a monoclonal IgG2c against Forssman antigen¹¹, demonstrated Forssman antigen on the apical surface of about 50% of the cells in the mixed monolayer under both growth conditions. The boundary between stained and unstained cells was sharp. Thus, the endogenous glycolipid

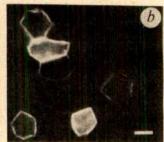

Fig. 2 The fluorescent phospholipid N-rhodamine phosphatidylethanolamine (N-Rh-PE) does not diffuse to neighbouring cells in a monolayer of MDCK strain I cells grown on nitrocellulose filters. N-Rh-PE, a water-insoluble lipid¹², was fused into the apical plasma membrane^{7,8} using unilamellar liposomes containing the fluorescent lipid equally distributed over both bilayer leaflets16 The cells were infected with 4 plaque-forming units per cell of influenza N virus and infection allowed to proceed for 4 h at 37 °C. The liposomes were prepared by reverse-phase evaporation 19 from egg phosphatidylcholine, egg phosphatidylethanolamine, cholesterol, ganglioside $G_{\rm D1a}$ and N-Rh-PE (25:25:50:5:1, mol/mol). 20 nmol total lipid was added in 500 µl of serum-free medium to a monolayer of 3 × 106 cells. After 30 min at 0 °C, fusion was initiated by treatment with a serum-free medium buffered at pH 5.0 by 20 mM succinate, at 37 °C for 60 s. The cells were then returned to pH 7.4 medium and put on ice. Treatment of the cell surface with trypsin, necessary to cleave the haemagglutinin to its fusogenic form^{7,8}, was omitted because in strain I MDCK cells the haemagglutinin is cleaved spontaneously by a secreted protease (G.vanM., unpublished observations). Electrical resistance before infection was $6 \pm 2 \times 10^3 \,\Omega$ cm² (n = 3), and after the complete procedure it was $1.2 \pm 0.2 \times 10^3 \Omega \text{ cm}^2$ (n = 6). The microscope, equipped with a water immersion objective, was focused at the apical surface of the living cells (a) or halfway down the lateral surface (b), after liposome-cell fusion. Scale bar, 10 μm.

could not pass from MDCK strain II cells to the apical surface of neighbouring MDCK strain I cells over a period of 96 h of co-culture at 37 °C.

As an alternative approach, we fused 7.8 fluorescent lipids into the apical plasma membrane of 50% or less of MDCK cells in a confluent monolayer and used a fluorescence microscope to observe whether the fluorescent lipid would move to non-fluorescent neighbour cells. For this, the fluorescent lipids dioleoyl N-rhodamine phosphatidylethanolamine (N-Rh-PE) or octadecyl rhodamine B (R18), which do not spontaneously exchange through the aqueous phase 12,13, were incorporated into liposomes. These liposomes were then added at 0 °C to the apical surface of MDCK cells infected with influenza virus. They were bound to the viral haemagglutinin glycoprotein expressed on the apical surface of these cells by including a haemagglutinin receptor into the liposomal membrane, the GDIa ganglioside. Fusion was induced by a short treatment (60 s) at low pH (5.0) and 37 °C7.8, after which the medium was readjusted to pH 7.4 and 0 °C. Lipid insertion was limited to a fraction of the cells in the epithelial monolayer by infecting the cells with a low multiplicity of influenza virus; in this way, only part of the cells in the monolayer became infected. Only the infected cells subsequently bound and fused liposomes.

MDCK strain I cells were selected for one set of experiments because they develop monolayers possessing a high electrical resistance (>2,000 Ω cm²) when grown on a permeable support¹⁴, and this resistance can be used to assay the intactness of the tight junctions during the experiment¹⁰,¹⁵. The fluorescent phospholipid N-Rh-PE was fused into the apical plasma membrane of about 50% of the MDCK strain I cells in a confluent monolayer (Fig. 2). Fusion was evident from the fact that the fluorescent phospholipid reached the basolateral surface (Fig. 2b). This process will be demonstrated and discussed in more detail elsewhere¹⁶. Fusion was also assayed by the hydrolysis of liposomal cholesterol oleate by a cellular enzyme⁶. The

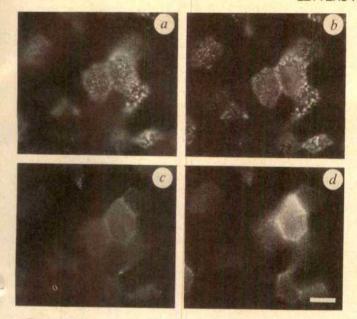

Fig. 3 The fluorescent lipid probe octadecyl rhodamine B (R18) does not pass from cell to cell in a monolayer of MDCK strain II cells on nitrocellulose filters. R18, a positively charged rhodamine lipid unable to exchange spontaneously between membranes13 was fused into the apical plasma membrane as in Fig. 2 with the following differences. At 5 h after infection with 4 plaque-forming units per cell of influenza N virus, the cell monolayer was treated with trypsin as described elsewhere 7.8. Large unilamellar liposomes were prepared by octyl β -D-glucoside dialysis from the same lipids as used in Fig. 2 but containing 1 mol % R18 instead of N-Rh-PE. The microscope was focused from the apical surface (a) down the lateral surface (b-d). The contorted orthogonal morphology of the columnar MDCK cells on nitrocellulose filters is clearly visible. Scale bar, 10 µm.

electrical resistance of the monolayer was $1,200 \pm 160 \,\Omega$ cm² (n=6) after the experiment, indicating that the tight junctions between the cells were essentially intact. In comparison, the electrical resistance across an intact polarized monolayer of strain II MDCK cells without virus infection was 160 Ω cm². Under these circumstances, no spreading of the fluorescent phospholipid to the adjacent non-infected cells was observed. Bright and dark cells remained juxtaposed in the cell monolayer for hours.

Similar experiments were performed on low-resistance MDCK strain II cells using another lipid probe (Fig. 3). The fluorescent lipid R18 was fused into the apical plasma membrane. R18 differs from N-Rh-PE in that it carries one positive charge at neutral pH. As a criterion for intactness of the tight junction, the impermeability of the tight junction to antibodies was monitored as described above. The antibody rrl against the lateral protein uvomorulin¹⁰ was unable to label its antigen throughout the experiment. Like N-Rh-PE, R18 remained confined to the cells into which it had been fused (Fig. 3a-d). No spreading from bright to dark cells was observed for hours at 0 °C.

We have presented evidence that three different types of lipids present in the apical plasma membrane domain are unable to diffuse into the apical membrane of adjacent cells. Dragsten et al.17 earlier observed that after partitioning water-soluble fluorescent probes into a monolayer of epithelial cells and bleaching one cell completely, no fluorescence returned into this black cell from the surrounding bright cells. In our experiments we used endogenous glycolipids and water-insoluble probes introduced by fusion, which we know are present in the outer leaflet of the apical membrane. We avoided the potentially damaging effects of photobleaching by observing mixed populations of cells containing and lacking the lipid studied. Finally, we also demonstrated that the tight junctions between relevant

cells were intact according to two criteria, both the transepithelial electrical resistance and the impermeability of the cell monolayer to antibodies. Moreover, we have tested the behaviour of the lipids at both 37 °C and 0 °C. Our observations argue against a continuity between the external leaflets of the apical plasma membrane in adjacent epithelial cells. The results are thus difficult to reconcile with the hexagonal lipid model of tight junction structure where the outer leaflets of the plasma membranes of neighbouring cells are fused3,4. It seems more likely that proteins which are part of the tight junction structure 10,18 bring the plasma membranes of adjacent cells very close together but do not induce a partial fusion. This would also be more consistent with the fact that the tight junction, as a barrier to ion diffusion between cells, displays ion selectivity

We thank Thomas Gabran and Hilkka Virta for technical assistance, Annie Steiner and Anne Walter for typing the manuscript, Arnoud Sonnenberg (Netherlands Cancer Institute, Amsterdam) for the monoclonal anti-Forssman and Jean Davoust, Stephen Fuller, Henrik Garoff and Wieland Huttner for critically reading the manuscript and for helpful suggestions.

Synthetic peptides as nuclear localization signals

David S. Goldfarb*, Jean Gariépy†, Gary Schoolnik† & Roger D. Kornberg*

Departments of * Cell Biology and † Medical Microbiology, Stanford University School of Medicine, Stanford, California 943-5, USA

The nuclear envelope defines a compartment boundary which is penetrated by pores that mediate a remarkable transport process. Precursor RNAs are retained in the nucleus, while processed messenger RNA1, transfer RNA2 and ribosomal subunits3 are transported to the cytoplasm. Proteins destined for the nucleus become localized soon after synthesis and again following mitosis, while cytoplasmic proteins are excluded4. The process is highly specific: a single base change in vertebrate initiator tRNA Met (tRNA_i^{Met}) reduces the rate of export 20-fold⁵; a point mutation within the simian virus 40 (SV40) large-T antigen, converting Lys 128 to Thr (ref. 6) or Asn (ref. 7), prevents import. Lys 128 lies within a short 'signal' sequence which, when fused to large non-nuclear proteins, causes their accumulation in nuclei6-Regions of other eukaryotic proteins also seem to contain nuclear localization signals, although a single consensus sequence has not emerged9-13. We report here that a synthetic peptide containing 10 residues of large-T antigen sequence serves as a nuclear localization signal when cross-linked to bovine serum albumin (BSA) or immunoglobulin G (IgG) and microinjected in Xenopus oocytes. Substitution of Thr at the position of Lys 128 in this peptide

toethanol, 50 mM Tris-HCl pH 6.8, boiled and centrifuged. Supernatants (5,000 c.p.m.) were analysed by electrophoresis in a SDS-10% polyacrylamide gel²¹ and autoradiography. Methods. Peptides were prepared using a Beckman 990B synthesizer as described previously^{22,23}. Crude peptides in 0.1% aqueous trifluoroacetic acid were purified by HPLC on a C18 Ultrasphere ODS reverse-phase column (Altex; 250×10 mm i.d.). The composition and concentration of purified peptides were verified by amino-acid analysis. Peptides were cross-linked to proteins (BSA, Pentex Fraction V, Miles Scientific, or mouse monoclonal antibody My1, directed against Dictyostelium discoideum myosin²⁴) as follows. Protein (10 mg in 2 ml of PBS²⁵) was treated with m-maleimidobenzoyl-N-hydroxysuccinimide ester (Pierce; 5 mg in 0.5 ml of dimethylformamide) for 1 h at 20 °C. Modified protein was purified by filtration through Sephadex G-25 in 0.1 M sodium phosphate, pH 6.0. Peptide solution (5 mg ml⁻¹ in 0.1 M sodium phosphate, pH 6.0) was added dropwise and allowed to react for 1 h at 20 °C. Peptide-linked protein was purified by filtration through Sephadex G-25 in 0.1 M NH₄HCO₃. Numbers of peptides per molecule of BSA, determined by SDS-gel electrophoresis (and by amino-acid analysis) were: P(Lys), 5-22 (7.2 ± 4.5); P(Thr), 7-21 (11.5 \pm 6.7); P(H2B), 13-25. Peptide-linked proteins were labelled by treatment with 125 I-sodium iodide and Enzymobeads (BioRad), filtered through Sephadex G-25 in PBS²⁶, and concentrated with the use of Centricon-30 filters (Amicon). Specific activities ranged from 1,500 to 2,500 c.p.m. ng⁻¹. Labelled proteins were microinjected with bevelled glass needles (10-20 µm o.d.)

Fig. 1 a, Nuclear accumulation of peptide-linked BSA.

P(Lys)-BSA; \bigcirc , P(Thr)-BSA; \blacktriangle , P(H2B)-BSA; \triangle , BSA. Each point represents a mean of determinations on 6-10 oocytes, injected with ~5 ng of ¹²⁵I-protein per oocyte. Incubations were at 18 °C, except for the point for P(Lys)-BSA at zero time, which was taken at 0 °C. The ratio of nuclear to cytoplasmic ¹²⁵I-protein concentration, ¹²⁵I-N/[¹²⁵I]C, was calculated from the expression (% c.p.m. nuclear/12)/(% c.p.m. cytoplasmic/88), assuming that the nucleus contains 12% of the accessible aqueous volume of an oocyte ¹⁶. b, Stability of ¹²⁵I-P(Lys)-BSA following microinjection in oocytes and incubation for 12 h at 18 °C. Intact oocytes (lane 1), starting ¹²⁵I-P(Lys)-BSA (lane 2), oocyte nuclei (lane 3) and oocyte cytoplasm (lane 4) were dispersed in 10% SDS, 100 mM β -mercap-

renders it six- to sevenfold less effective. The uptake of peptidelinked BSA is saturable, and the rate is diminished by co-injection of free peptide. These findings are indicative of a receptor-mediated uptake process. With the use of anti-peptide antibodies, a family of proteins is revealed in nuclear but not cytoplasmic extracts of human lymphocytes which contain large-T antigen-like sequences.

Deletion analyses from either end of a large-T antigen sequence incorporated in fusion proteins have defined two minimal segments required for nuclear localization, with a region of overlap containing Lys 128 (ref. 8). The signal peptide synthesized for use in the present study, designated P(Lys), spanned these minimal segments (Table 1). P(Thr) contained the substitution of Thr for Lys 128 (ref. 6). A third peptide, P(H2B), contained residues 1-17 of Xenopus histone H2B (ref. 14), but presumably no nuclear localization signal, as assessed by microinjection experiments⁴ with residues 1-58 and genetic studies of the corresponding region of yeast histone H2B (R. Moreland and L. Hereford, personal communication). All three peptides included carboxy-terminal tyrosine and cysteine residues, for radioiodination and chemical cross-linking, respectively. Cross-linking was accomplished with a sulphydryl-toamino group reagent, and gave 10-20 peptides per molecule of BSA (see Fig. 1 legend).

On injection of SV40 DNA in Xenopus oocytes, large-T antigen accumulates in the nucleus, showing that a large-T antigen signal sequence is recognized by the *Xenopus* nuclear uptake apparatus¹⁵. We find that P(Lys)-BSA, bearing large-T antigen signal peptides, also accumulates, reaching a six to sevenfold higher concentration in the nucleus than in the cytoplasm (Fig. 1a). By contrast, P(Thr)-BSA only equilibrates between nucleus and cytoplasm, and both P(H2B)-BSA and unmodified BSA (see also ref. 16) are virtually excluded from the nucleus (Fig. 1a). Similar results were obtained with P(Lys)- and P(Thr)-IgG (data not shown). Entry of P(Lys)-BSA into nuclei, as opposed to binding at the surface, was confirmed by fluore-scein-labelling and epi-fluorescence microscopy of frozen thin

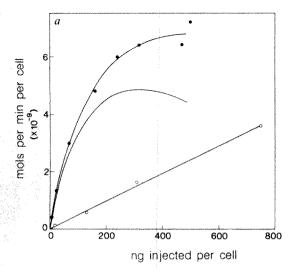

along the line dividing the animal and vegetal hemispheres towards the centre of stage 5 or 6 Xenopus oocytes, maintained in modified Barth's saline at 18 °C as described elsewhere²⁶. Following incubation, oocytes were suspended in 20% trichloroacetic acid on ice and dissected with forceps¹⁶. ¹²⁵I in nucleus and cytoplasm was

determined with an LKB 1260 Multigamma II counter. Protein concentrations were determined as described by Bradford²⁷.

Table 1 Synthetic peptides used in this work

Bars above the sequence of P(Lys) indicate minimal segments required for nuclear localization of SV40 large-T antigen⁸. Carboxy-terminal tyrosine and cysteine residues were added for radioiodination and chemical cross-linking, respectively.

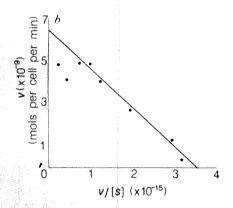

Fig. 2 a, Initial rate of nuclear accumulation of P(Lys)-BSA as a function of amount injected. ♠, P(Lys)-BSA; ○, BSA. Each initial rate was determined from measurements on at least two groups of six to eight oocytes, injected with ¹²⁵I-P(Lys)-BSA or ¹²⁵I-BSA, incubated for 10-45 min at 25 °C, and processed as for Fig. 1. The central curve (no data points) represents the difference between the two experimentally determined curves. b, Eadie-Hofstee plot of data from a. Reaction velocites (v) were derived from the initial rate data for P(Lys)-BSA by subtraction of values from the curve for BSA. Concentrations ([S]) of P(Lys)-BSA in oocytes were calculated as described for Table 2.

sections (data not shown). P(Lys)-BSA isolated from nuclei was indistinguishable in size from starting material (Fig. 1b) and therefore had not entered as proteolytic fragments. We conclude that the attachment of signal peptides to the surface of proteins too large to enter the nucleus by diffusion is sufficient to effect their nuclear localization, and moreover, that the process is signal-sequence-specific, with no simple dependence on amino-acid composition (for example, on net positive charge^{17,18}).

The nuclear accumulation of P(Lys)-BSA showed saturation kinetics (Fig. 2a), when corrected for entry into the nucleus by diffusion 19 , which became appreciable when large amounts of material were injected. (Rates of entry by diffusion were determined with unmodified BSA, and may represent slight overestimates for P(Lys)-BSA, which is expected to enter more slowly due to its larger size.) An Eadie-Hofstee plot was linear (Fig. 2b), with intercepts corresponding to a $K_{\rm M}$ of 1.8×10^{-6} M and $V_{\rm max}$ of 6.4×10^{9} molecules per cell per min. (Rates of nuclear accumulation varied, depending on the batch of oocytes and extent of iodination of the protein, so the values of $K_{\rm M}$ and $V_{\rm max}$ should be regarded as approximate.) Deviations from linearity at the two highest values of substrate concentration probably reflect the inaccuracy of the correction for diffusion.

The peptide-linked proteins used in this work differ from natural substrates for nuclear transport in possessing multiple signal sequences, and the question arises of whether a single peptide would be effective. We investigated this question by co-injecting P(Lys)-BSA with excess free peptide (Table 2).

Table 2 Effect of free peptide on nuclear accumulation of peptidelinked BSA

Free peptide	Expt 1	Expt 2
None	23.6 ± 8.2	27.1 ± 11.1
P(Lys)	10.9 ± 3.4	11.3 ± 4.1
•	(0.01 < P < 0.02)	(0.02 < P < 0.05)
P(Thr)	19.0 ± 4.4	19.0 ± 6.9
	(0.02 < P < 0.05)	(0.05 < P < 0.1)
P(H2B)	-	25.1 ± 8.7
		(0.2 < P < 0.5)

Approximately 5 ng of 125 I-P(Lys)-BSA (6×10^{-5} nmol) was injected alone or with the free peptide (0.5 nmol) indicated in 16-18 oocytes. Approximate concentrations of P(Lys)-BSA and free peptide in an oocyte were 1×10^{-7} and 0.9×10^{-3} M, respectively, based on an accessible aqueous volume of $0.5\,\mu$ l (one-third) 16 of a total volume of $1.5\,\mu$ l) plus an average volume injected of 60 nl. Following incubation for 40 min at $18\,^{\circ}$ C, 125 I in nucleus and cytoplasm were determined as in Fig. 1. Data are expressed as the per cent of the total counts found in the nucleus. The probability (P) that added peptide did not affect uptake was determined with a two-tailed t-test.

Nuclear accumulation of the peptide-linked protein was markedly reduced by free P(Lys) and to a lesser extent by P(Thr). Only the rate and not the final extent of nuclear accumulation was affected (data not shown). Co-injection of P(H2B) caused no significant reduction in rate, arguing against indirect effects of the peptide preparations. We conclude that free peptide interacts specifically with a component of the nuclear transport apparatus, although the affinity of the interaction is low, as 1 mM peptide is required for $\sim 50\%$ inhibition of transport. The difference between the micromolar $K_{\rm M}$ for P(Lys)-BSA and the much lower affinity for free peptide may reflect a multivalent interaction of the peptide-linked protein (see ref. 18), but further work is needed to explain the discrepancy.

The saturation kinetics and effect of free peptide on nuclear transport are indicative of a limiting component of the uptake apparatus. This component may be a receptor for the signal peptide or it may interact with a receptor-signal peptide complex. The receptor may be diffusible, as in the case of 'signal recognition particle' in the synthesis of membrane and secreted proteins²⁰, or it may reside in the nuclear pore complex. Signal peptide may interact not only with this receptor but also with factors inside the nucleus. Thus, the apparent capacity of P(Thr)-linked proteins to enter but not accumulate in the nucleus may be explained either by their altered interaction with the receptor or by their lack of retention (for example, through binding) in the nucleus. Further modifications of the signal peptide sequence and kinetic analyses may help to distinguish between these possibilities.

A nuclear uptake receptor would presumably be general, recognizing signal sequences not only in large-T antigen but also in other nuclear proteins. We have used anti-signal peptide antibodies to investigate the occurrence of large-T-like sequences in other proteins. Antisera against P(Lys) reacted strongly with several nuclear proteins from human lymphocytes (Fig. 3). This strong reaction was abolished by pre-incubation of antisera with P(Lys) (two weakly reacting components at relative molecular mass $(M_{\rm r}) \sim 45,000~(45{\rm K})$ and 65K persisted). There was only a weak reaction with a small number of cytoplasmic proteins, and these appeared to correspond with nuclear proteins, which may have leaked from nuclei during isolation. These data are indicative of a family of proteins bearing homologous nuclear localization signals and sharing a common receptor. Conceivably, all nuclear proteins share the same receptor, whose

Fig. 3 Reaction of antiserum against P(Lys) with proteins from human lymphocytes. A SDS-10% polyacrylamide gel of cytoplasmic (lanes 1, 4) and nuclear (lanes 2, 3) extracts is shown before (lanes 3,4, stained with Coomassie blue) and after (lanes 1, 2) immunoblotting. M_r of markers from the top of the gel, are 200 K, 97.4 K, 68 K, 43 K, 25.7 K, 18.4 K.

Methods. MICH cells (an Epstein-Barr virus-immortalized human B-lymphocyte line, from Dr P. Parham, Stanford University) were grown in RPMI-1640 supplemented with 10% fetal bovine serum. Cells (6×108) were washed with cold phosphate-buffered saline and lysed by suspension in 14 ml of 0.34 M sucrose, 10 mM Tris-HCl pH 7.8, 2 mM MgCl₂, 1 mM CaCl₂, 0.2% NonidetP-40, 10 mM β-mercaptoethanol, 0.5 mM phenylmethysulphonyl fluoride (PMSF). One ml of the lysate was centrifuged (Eppendorf) for 5 min, and the supernatant was retained as cytoplasmic extract. To the remaining lysate was added 14 ml of buffer B (2 M sucrose, 10 mM Tris-HCl pH 7.8, 5 mM MgCl₂, 10 mM β-mercaptoethanol, 0.5 mM PMSF), and the mixture was layered over 3 ml of buffer B and centrifuged for 50 min at 25,000 r.p.m. in a Beckman SW41 rotor. The pellet was suspended in 3 ml of 50 mM Tris-HCl pH 7.8, 0.1 M NaCl, 10 mM β-mercaptoethanol, 0.5 mM PMSF, and 2 ml of 2.5 M KCl was added to give nuclear extract. The cytoplasmic and nuclear extracts were centrifuged for 30 min at 50,000 r.p.m. in a Beckman TL-100 ultracentrifuge. Aliquots (30 µg of protein) of the supernatants were fractionated in polyacrylamide gels and electroblotted onto a nitrocellulose filter, and the filter was washed in 0.9% NaCl, 10 mM Na-phosphate, 0.05% Tween-20 pH 7.4 and incubated for 1 h with anti-P(Lys) antiserum (1:500 dilution). Antibody bound to the filter was detected with the Vectastain ABC horseradish peroxidase system as described by the manufacturer (Vector). Anti-P(Lys) antiserum was obtained from rabbits 10 days after a second injection with 200 µg of P(Lys)-thyroglobulin (prepared as for Fig. 1 with bovine thyroglobulin type 1 (Sigma), injected first with Freund's complete adjuvant and 14 days later with incomplete adjuvant).

specificity is broader than that of the anti-peptide antibodies used here. Alternatively, there may be additional receptors for other classes of nuclear protein bearing different signal

We thank Dr Peter Sargent for access to his Xenopus colony, Dr Peter Parham for monoclonal anti-myosin antibody, and Alan Sachs for discussion. Loss of genes on chromosome 22 in tumorigenesis of human acoustic neuroma

Bernd R. Seizinger*, Robert L. Martuza† & James F. Gusella*

* Neurogenetics Laboratory, Massachusetts General Hospital and Department of Genetics, Harvard Medical School, Boston, Massachusetts 02114, USA

† Department of Surgery, Neurosurgery Service, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts 02114, USA

The application of recombinant DNA techniques has identified two fundamental mechanisms of tumorigenesis in man. The first involves a qualitative or quantitative change in an oncogene (see ref. 1 for review). In the second, discovered in embryonal tumours, a primary mutation occurs which is recessive at the cellular level to the normal allele. The growth of a tumour ensues only after a secondary change, such as chromosome loss or mitotic recombination, eliminates the normal allele, thereby unmasking the altered allele2-7. Because its effect is recessive, the primary mutation may also occur and be transmitted in the germ line, resulting in a familial pattern for the disease. In familial cases, independent bilateral tumours are common, since the tumours result from a single event-loss of the normal genes-which can occur in any cell. This contrasts with non-familial (sporadic) cases where solitary tumours result from the infrequent occurrence of two rare events within the same cell²⁻⁷. By a molecular genetic approach we have now shown that acoustic neuroma, one of the most common tumours of the human nervous system8, is specifically associated with loss of genes on human chromosome 22 and may result from the mechanism of tumorigenesis discovered in embryonal tumours. This finding might provide a clue to the chromosomal location of the defective gene in bilateral acoustic neurofibromatosis, an autosomal dominant disorder with the hallmark of bilateral acoustic neuromas 9-12. In view of the frequent occurrence of meningiomas in patients with bilateral acoustic neurofibromatosis and the association of meningioma with loss of chromosome 22 previously reported in cytogenetic studies 13-15, we suggest that a common event underlies tumorigenesis in acoustic neuroma and meningioma.

Chr, chromosome. Tumour and normal DNA from acoustic neuroma patients was digested with the indicated restriction enzymes, fractionated by agarose gel electrophoresis, transferred to nylon membranes, and hybridized to probes for the indicated loci as described in Fig. 1. In addition to the three chromosome 22 probes are the probes from other chromosomes were used: N8C6 (NGFB)^{21,22}, G8 and R7 (D4S10)^{23,24}, G9 (D4S35)²⁵, Dry5-1 (D10S1)²⁶, pEl6.6 (HRAS1)²⁷, pHINS321 (INS)²⁸, pJ19.4 (D11S17)²⁶, p640 (KRAS2)²⁷, p7F12 (D13S1)²⁹, p1E8 (D13S4)²⁹, pHUB8 (D13S5)³⁰ pHU26 (D13S7)³⁰, pAW101 (D14S1)³⁵, C-H800 (GH)³², B74 (D18S3)²⁶, pC3 (C3)³³ and pGSH8 (D21S17)³⁴. These probes are known to reveal RFLPs in human genomic DNA digested with the indicated restriction enzymes. The phenotype observed in the tumour DNA is shown for every case where the blood DNA displayed heterozygosity: '12' indicates heterozygosity (even though different pairs of alleles may be present for certain multi-allele markers), '1' indicates continued presence of the larger allelic restriction fragment and loss of the smaller allelic fragment relative to normal tissue DNA, and '2' indicates continued presence of the smaller allelic restriction fragment and loss of the larger fragment. Where the normal DNA was tested but was uninformative because it did not display heterozygosity a '-' has been entered to simplify consideration of the data. The absence of an entry indicates that a marker was not tested or did not give a readable result for that particular patient.

Acoustic neuroma (also called vestibular schwannoma or acoustic neurinoma) derives from Schwann cells enveloping the vestibular branch of the vestibulocochlear nerve¹⁶. The majority of acoustic neuromas occur as solitary non-inherited unilateral tumours. By contrast, bilateral tumours are the hallmark of the familial cases of acoustic neuroma that characterize central or 'bilateral acoustic' neurofibromatosis⁹⁻¹². The differences in presentation of sporadic and familial cases of acoustic neuroma are reminiscent of retinoblastoma and Wilms' tumour, two cancers for which loss of a particular chromosomal region (13q and 11p respectively) has been implicated in tumour development²⁻⁷.

We therefore used polymorphic DNA markers to search for similar loss of particular chromosome regions in acoustic neuroma. DNA was isolated from primary acoustic neuromas and corresponding leukocytes from 21 patients (5 male, 16 female). The frequency of both meningiomas and acoustic neuromas in bilateral acoustic neurofibromatosis, and the loss of chromosome 22 previously reported in cytogenetic investigations of meningioma¹³⁻¹⁵ prompted us to focus our initial efforts on DNA markers for chromosome 22. We typed genomic DNA with three polymorphic chromosome 22 markers: SIS, the platelet derived growth factor locus homologous to the sis oncogene mapping to 22q12.3-13.1; D22SI, an anonymous DNA locus detected by probe pMS3-18 mapping to 22pter-q13; and IGLC, the λ immunoglobulin constant region at 22q11. The results of this analysis are presented in Table 1.

Sixteen patients were heterozygous in their normal tissue for at least one of the three polymorphic DNA markers and were consequently informative for determining whether loss of

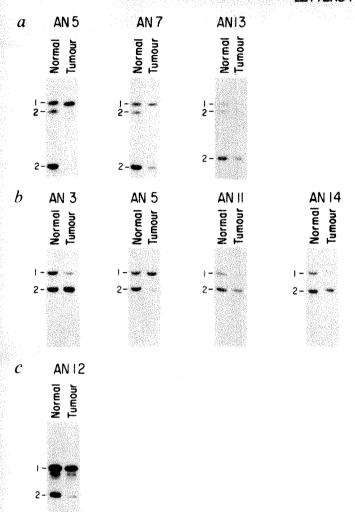

Fig. 1 Loss of constitutional heterozygosity of loci on human chromosome 22 in acoustic neuromas. Patient designations are shown above the autoradiograms. Numbers on the left indicate the observed alleles, with '1' and '2' referring to the larger and smaller allelic restriction fragments respectively. Southern blots were hybridized²² to ³²P-labelled DNA probes for the following loci on chromosome 22: a, Psis.1 (Oncor) (SIS oncogene); b, pMS3-18 (D22S1); c, HuAC2 (IGLC). Psis.1 reveals a RFLP with fragments of 21 kilobases (kb) ('1'-allele), and 14.5 and 6.5 kb ('2'-allele) in HindIII-digested human genomic DNA^{35,36}. pMS3-18 probe detects a RFLP in BglII-digested human DNA, with fragments of 9.5 kb ('1'-allele) and 6.5 kb ('2'-allele)³⁷. The HuλC2 probe reveals a multi-allele RFLP represented by fragments of 8 kb, 13 kb, 18 kb and 23 kb in EcoRI-digested human genomic DNA²⁶. To simplify the nomenclature, the higher relative molecular mass allele is called the '1'-allele, whereas the lower relative molecular mass allele is termed the '2'-allele in each case. Methods. High relative molecular mass DNA was isolated from surgical tumour specimens and corresponding normal tissue (peripheral leukocytes). The tumour specimens which had been immediately frozen on dry ice after operation, were rapidly washed, rinsed and suspended overnight at 37 °C in a TNE-SDS-proteinase K solution (10 mM Tris, pH 8.0; 100 mM NaCl; 1 mM EDTA, 1% SDS; 200 μg ml⁻¹ proteinase K). Nuclei from peripheral leukocytes were isolated by gently homogenizing peripheral venous blood in a solution containing 0.64 M sucrose, 20 mM Tris, 10 mM MgCl₂, 5% (v/v) Triton X-100 pH 7.6 at 4 °C. The isolated nuclei were subsequently incubated overnight at 37 °C in the TNE-SDSproteinase K-solution. DNA from tumour and leukocyte tissue samples was purified by phenol and chloroform extraction²³. Approximately 5 μ g of DNA was digested to completion with the restriction enzymes HindIII, BglII or EcoRI (New England Biolabs). The resulting DNA fragments were fractionated by agarose gel electrophoresis and transferred to nylon membrane

constitutional heterozygosity had occurred in their respective tumour tissue. Seven of the 16 informative cases (44%) showed loss or marked reduction in the intensity of one of the two alleles in their tumour tissue (Table 1). These cases are displayed in Fig. 1. When analysed by densitometry, the hybridization signals corresponding to the deleted allele were estimated to be diminished by 60% (patient AN3), 86% (AN5), 75% (AN7), 73% (AN11), 75% (AN12), >90% (AN13) and 78% (AN14), respectively. The remaining hybridization signals in the tumour DNAs might be due to contaminating non-tumour cells (vascular or connective tissue) which may be present in primary surgical specimens. Alternately, the acoustic neuromas might consist of a mosaic of cells with normal karyotype, and cells with monosomy for chromosome 22.

To distinguish among the different mitotic mechanisms that might have produced this loss of heterozygosity, the hybridization signals from Fig. 1 were compared with those obtained when the same filters were rehybridized with several probes for loci on other chromosomes. The results obtained are presented in Table 2. The ratio of the copy number of chromosome 22 between tumour and normal tissue was approximately 1:2 in all seven cases. This is indicative of 'true' loss of one copy of the chromosome 22 locus, rather than mitotic recombination, loss and reduplication, or gene conversion. Furthermore, patient AN5 was constitutionally heterozygous for two of the three chromosome 22 loci tested. Heterozygosity was lost at both loci in the corresponding tumour tissue, suggesting loss of the entire chromosome rather than a small partial deletion. None of these acoustic neuromas showed mitoses or other aggressive features upon pathological examination; neither did hemizygosity for chromosome 22 show any striking correlation with the patient's age, sex, tumour size or clinical course.

Loss of genes on chromosome 22 was not restricted to unilateral sporadic cases of acoustic neuromas, but was also observed in a tumour from patient AN14 who had bilateral acoustic neuromas. By analogy to inherited cases of retinoblastoma and Wilms' tumour, the defect in bilateral acoustic neurofibromatosis could map to chromosome 22. Tumours from patients AN10 and AN18, two cases of bilateral acoustic neurofibromatosis, did not show loss of heterozygosity for chromosome 22 markers. It should be noted, however, that alternative mitotic or mutational events leading to expression of a recessive disease gene could occur in either sporadic or familial cases without apparent loss of heterozygosity for the available DNA markers. For example, neither a new mutation, a gene conversion, nor a mitotic recombination with a breakpoint distal to the three markers would be recognized. It is conceivable that one or more of these three mechanisms have occurred in the nine tumours for which heterozygosity of the chromosome 22 markers was maintained.

The chromosomal specificity of the loss of heterozygosity in acoustic neuromas was investigated with several polymorphic DNA markers for 11 other chromosomes (Table 1). In each case where constitutional heterozygosity was observed, heterozygosity was also maintained in the corresponding tumour tissue. Thus, acoustic neuromas exhibit a remarkable genome stability, with chromosomal losses being highly specific to chromosome 22. The data in Table 1 also provide assurance that the differences between tumour and normal DNA on chromosome 22 did not arise from simply mispairing of the samples or unreliability

Table 2 Quantitative densitometry of probe hybridization for acoustic neuromas losing heterozygosity on chromosome 22

		Chromosome 22		
Patient	Tissue	Control chromosome	Tumour Normal

AN14	Acoustic neuroma	0.09	0.51	
	Leukocytes	0.17		

Densitometry of autoradiograms is subject to a number of variables. Therefore, to determine whether loss of one allele for chromosome 22 was associated with duplication of the remaining allele, it was necessary to control for these variations by normalizing the data for chromosome 22 probes to that obtained from the same blots using probes for other chromosomes. Southern blots which had been hybridized to probes for chromosome 22 (Fig. 1) were freed of these probes in distilled water for 2 h at 65 °C and rehybridized with probes for loci on other chromosomes ('Control chromosomes'): (1) D4S10 on chromosome 4p for AN7 and AN13; (2) D21S17 on chromosome 21q for AN3, AN5, AN11 and AN14; and (3) D13S5 on chromosome 13q for AN12. Heterozygosity for RFLPs of these markers frequently provided clear confirmation that they were not deleted in the tumor DNA. The autoradiograms from all hybridizations were analysed by scanning densitometry with an LKB Ultrascan XL. The peak areas corresponding to each hybridization signal were calculated by electronic integration. In order to determine that the approach of normalizing the hybridization signals yielded reliable results, we first compared hybridization signals for pairs of markers from other chromosomes (selected from the markers used in Table 1) for which heterozygosity in the tumours was maintained. These invariably gave constant ratios for tumour and normal DNA. We then determined whether any chromosome 22 alleles had been duplicated in the tumours by normalizing hybridization signals specific to chromosome 22 relative to hybridization signals for control chromosome probes in the same sample, and then obtaining a ratio of the normalized values for each tumour/normal tissue pair.

of the applied techniques. Indeed, all data in Table 1 with probes detecting restriction fragment length polymorphisms (RFLPs) in HindIII, BgIII and EcoRI digested DNA were obtained by rehybridizing the respective Southern blot filters already used for studies on chromosome 22.

The finding that acoustic neuromas specifically lose genes on chromosome 22 has several major implications. It extends the concept that specific somatic loss of constitutional heterozygosity can be a mechanism of tumorigenesis by demonstrating that it can operate in neural crest-derived tumours of the adult nervous system. It suggests that a similar mechanism is involved in development and growth of acoustic neuromas and meningiomas since the latter are also associated with loss of chromosome 2213-15 and both tumours occur frequently in bilateral acoustic neurofibromatosis⁹⁻¹². Of particular interest, this result may lead to the chromosomal localization of the defect causing bilateral acoustic neurofibromatosis, a serious genetic disorder that can lead to deafness or other neurological morbidity or mortality within the first few decades of life⁹⁻¹². Retinoblastoma and Wilms' tumour have become models for the concept that chromosomal mechanisms may serve to unmask recessive mutant alleles by elimination of the wild-type gene²⁻⁷. Unilateral occurrence of acoustic neuromas in sporadic cases, and bilateral tumour formation as the hallmark of the inherited form (bilateral acoustic neurofibromatosis) agree well with this model. Thus, genes on chromosome 22 may play a part in acoustic neuroma analogous to that of genes on chromosomes 11 and 13 in Wilms tumour and retinoblastoma, respectively. This would suggest that chromosome 22 contains a gene important for the development of acoustic neuromas that is transmitted in its defective form in bilateral acoustic neurofibromatosis.

The region of 11p associated with Wilms' tumour has more recently been tied to rhabdomyosarcoma and hepatoblastoma All three of these rare embryonal cancers cluster in the Beckwith-Wiedemann syndrome¹⁷. Similarly, the region of 13q implicated in retinoblastoma has now been associated with osteosarcoma¹⁸. The human genome may contain a limited number of such loci whose defective alleles predispose to tumour formation in particular tissues. The striking frequency of clinical association of acoustic neuromas and meningiomas in bilateral acoustic neurofibromatosis 9-12 and the observation that meningioma tissue can be adjacent to or within acoustic neuroma tissue 19,20 suggests that the selective loss of genes on chromosome 22 in both tumours is not pure coincidence but reflects a common mechanism of tumorigenesis.

We thank Dr R. Ojemann and the Massachusetts General Hospital neurosurgical staff for their assistance in providing specimens, Dr S. de la Monte for assistance in pathological interpretation, and K. Dashner and K. Riley for technical assistance. We thank the following scientists for providing DNA probes: Drs A. Ullrich, J. Habener, T. Dryja, G. Bell, C. Shih, R. Weinberg, R. White, H. Goodman, J. L. Mandel, G. Fey, G. Stewart and P. Leder. Tissue-specific expression of the human tropomyosin gene involved in the generation of the *trk* oncogene

Fernando C. Reinach* & Alexander R. MacLeod

* Present address: Departmento Bioquimica, Instituto Quimica, Universidade de Sao Paulo, Caixa Postal 20.780, CEP 01489, Sao Paulo SP, Brazil.

The trk oncogene is a human transforming gene generated by the fusion of tropomyosin gene sequences to a truncated tyrosine kinase receptor gene1. We have now characterized the normal tropomyosin gene from which the trk oncogene is derived. At least two different transcripts are expressed by this gene using a tissue-specific alternative messenger RNA splicing mechanism: a 2.5-kilobase (kb) mRNA encoding a 248-amino-acid tropomyosin in human fibroblasts and a 1.3-kb mRNA encoding a 285-amino-acid tropomyosin in human skeletal muscle. The rearrangement which generates the trk oncogene preserves most of the tropomyosincoding sequences of the normal gene, including exons alternatively spliced in muscle and non-muscle tissue. We therefore expect the trk oncogene to show a tissue-specific pattern of transforming activity. Correct expression of the trk oncogene can occur only in non-muscle tissues. In muscle tissue the oncogene would almost certainly be inactive, as splicing according to the alternative muscle pattern aborts synthesis of the tryosine kinase domain.

We have described an RNA-copy pseudogene hTM_{nm} -1 which defines a 2.5-kb-mRNA encoding a 248-amino-acid tropomyosin in human fibroblasts². The pseudogene hTM_{nm} -1 is colinear with the 2.5-kb fibroblast mRNA and very closely related but not identical in sequence to it. Similarly, the tropomyosin-coding sequences of trk were found to be very closely related but not identical to hTM_{nm} -1 (ref. 1). This suggests that the RNA-copy pseudogene hTM_{nm} -1, the 2.5-kb fibroblast mRNA and the tropomyosin-coding sequences of trk all originate from a common tropomyosin gene which we will call the hTM_{nm} structural gene. This is confirmed by DNA sequence analysis of complementary DNA clones of the 2.5-kb mRNA (not shown) which demonstrates that the tropomyosin-coding sequences of trk are identical to those of the 2.5-kb mRNA.

Tropomyosin genes have been shown to express structurally distinct protein isoforms by a tissue-specific alternative mRNA splicing mechanism³⁻⁶. We have therefore examined the expression of the hTM_{nm} structural gene in different tissues by hybridization of hTM_{nm} -1 to blots of human fibroblast and muscle RNA (Fig. 1). The 2.5-kb mRNA characterized pre-

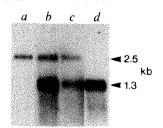

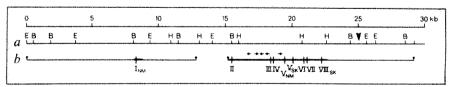

Fig. 1 Northern blot analysis of human non-muscle and muscle RNA. Poly (A)-containing RNA (0.5 μ g) from cultured MRC-5 fibroblasts (lane a), adult heart muscle (lane b), fetal skeletal muscle (lane c) and adult skeletal (leg) muscle (lane d) was denatured with formaldehyde, subjected to electrophoresis and blotted onto nitrocellulose⁹. The filter was probed with M29, a probe derived² from the coding region of hTM_{nm} -1. Hybridization was carried out under stringent conditions (50% formamide, 42 °C) followed by washing in 0.2×SSC at 67 °C. The human fibroblast and adult skeletal muscle tracks were exposed to film for 24 h, the other tracks for 96 h. Sizes of the mRNAs were determined by comparison with known mRNA standards.

viously is found in the fibroblast, heart and fetal muscle RNA samples. In all the muscle preparations an additional 1.3-kb mRNA is apparent which cross-hybridizes with hTM_{nm} -1 under stringent conditions. This transcript is particularly abundant in adult skeletal muscle, in which the 2.5-kb fibroblast mRNA is undetectable. Clones containing the complete coding sequence of the 1.3-kb muscle mRNA were isolated from a library of human skeletal muscle cDNA using hTM_{nm} -1 as a probe (Fig. 2). The deduced protein sequence of this mRNA is 285 amino acids long (numbering from the initiator methionine) and is very closely related to the protein sequence of rabbit skeletal muscle α -tropomyosin⁷.

Comparison with the tropomyosin-coding sequences of trk reveals a very striking homology (Fig. 2). The two mRNAs encode distinct N-terminal protein sequences; that of the 1.3-kb mRNA is characteristic of a 284-amino-acid skeletal muscle tropomyosin while the N-terminal protein sequence of trk is characteristic of a 247-amino-acid cytoskeletal tropomyosin. However, the nucleotide sequences encoding amino acids 80-188 and 214-257 of the 1.3-kb muscle mRNA are identical to sequences found in trk and the 2.5-kb fibroblast mRNA. These two regions of sequence identity are interrupted by a short region of non-identity encoding amino acids 189-213 of the muscle tropomyosin. This pattern of regions of nucleotide sequence identity interrupted by regions of nucleotide sequence non-identity is characteristic of transcripts derived from a common structural gene by alternative mRNA splicing.

Fig. 2 Restriction map of a region of the hTM_{nm} structural gene. Probes derived from the pseudogene hTM_{nm}^{-1} were used to screen libraries of human fibroblast DNA. These libraries were constructed as described elsewhere² using partial digestion with Sau3A, HindIII or BgIII to generate the 15-20-kb DNA

fragments suitable for insertion into $\lambda 1059$ (ref. 12) or $\lambda 2001$ (ref. 13). Both clones were isolated from the partial BgIII library. a, Restriction enzyme mapping was carried out with BamHI (B), HindIII (H) and EcoRI (R). b, Positions of exons containing tropomyosin-encoding sequences. Although the clones do not overlap, a single BamHI fragment spanning the 2.5-kb gap was found in Southern blots of BamHI-digested human fibroblast DNA using single-copy probes from the isolates. The large arrow indicates the approximate point of divergence of the trk map from the normal hTM_{nm} gene; trk contains the BamHI site on the left of the arrow but does not contain the EcoRI sites on the right side of the arrow¹. The small arrows indicate the position and orientations of the Alu repeat sequences located by DNA sequencing. The thick lines indicate the regions sequenced, and the vertical bars indicate the positions of the exons within this sequence. Exons containing the trk and 2.5-kb fibroblast mRNA sequences were located by comparison of the DNA sequence with that of hTM_{nm}^{-1} . Exons containing other tropomyosin-coding sequences were identified by comparing three phase protein translations of the DNA sequence with all known tropomyosin sequences¹⁴ using the program DIAGON¹⁵. The trk sequence varies from the normal gene sequence at two positions (337 and 456), one of which (337) leads to a Lys \rightarrow Glu amino-acid replacement. Where it is possible to make the comparison, the 1.3-kb muscle mRNA sequence is identical, base for base, with the normal gene sequence.

1 3 6 796 1.3 ATM GGATTCCATTTGGGTCAGCCTGGCTGGTCCCCAAGGCATTAGGATGGGGGAGCAAAAAGCAACTTATGTATTTTCTTECACCOCCACCCC 7.3 4896 AAATTAAAATGTTAAGCTGCTGGAAAAAAAA

Fig. 3 Cloning and sequence analysis of the 1.3-kb skeletal muscle RNA transcript. A cDNA library of human skeletal muscle RNA in Agt10 was generated using procedures described in detail elsewhere^{6,10}. This was screened with the hTM_{nm}-1 and positive clones were taken for further analysis, subcloned into M13 mp18 and sequenced by the processive degradation procedure¹¹. This yielded the complete coding sequence of the 1.3-kb muscle mRNA (1.3 ATM) together with 57 bases of the 5'untranslated sequence and the complete 3'untranslated sequence. The deduced protein sequence is numbered by homology to rabbit skeletal muscle α -tropomyosin⁷. The sequence is shown compared with that of trk1. The coding sequences of trk are shown only where they differ from those of the 1.3-kb muscle mRNA.

This hypothesis is confirmed by analysis of genomic clones containing hTM_{nm} structural gene sequences. Two genomic clones, isolated by hybridization to $hTM_{nm^{-1}}$, were characterized by restriction enzyme mapping (Fig. 3) and DNA sequence analysis (not shown). Nine exons were found in the 7,900 bases sequenced, 8 of them, from exon II to exon VIIIsk, forming a single contiguous sequence. The regions of mRNA sequence encoded by these exons are shown in Fig. 2. As expected, the boundaries of the regions of sequence identity correspond to splice junctions defining exon boundaries (Fig. 2). The regions of identical sequence shared by the 1.3-kb muscle mRNA, 2.5-kb fibroblast mRNA and trk oncogene are found in exons II, III, IV, VI and VII. The two different sequences encoding amino acids 189-213 are found in two adjacent exons, one (exon V_{nm}) found in the trk and 2.5-kb fibroblast mRNA, the other (exon V_{sk}) found in the 1.3-kb muscle mRNA. The unique N-terminal sequences of trk and the 2.5-kb fibroblast mRNA are found in exon I_{nm}. The exons encoding the unique N-terminal sequences of the 1.3-kb muscle mRNA are not found in either of these genomic clones and are presumed to lie a considerable distance upstream of exon Inm. Similarly, exon VIIIsk, encoding the unique C-terminal 27 amino acids of the 1.3-kb muscle mRNA,

is found immediately downstream from the common exon VII sequence, although exon VIII_{nm}, encoding the unique C-terminal sequence of the 2.5-kb fibroblast mRNA, has not been found in these genomic clones and is presumed to lie far downstream

Our analyis indicates that the 1.3-kb muscle mRNA, 2.5-kb fibroblast mRNA and tropomyosin-coding sequences of trk are all derived from hTM_{nm} structural gene sequences. The 2.5-kb fibroblast mRNA and the 1.3-kb muscle mRNA are expressed by the normal hTM_{nm} structural gene using a tissue-specific alternative mRNA splicing mechanism. The trk oncogene is a recombinant of the hTM_{nm} structural gene with a tyrosine kinase receptor gene. Comparison of the genomic restriction map of trk with that of the normal hTM_{nm} gene indicates that the rearrangement has occurred downstream from exon VIII_{sk} (ref. 1 and M. Barbacid, personal communication). Thus, the oncogene preserves most of the tropomyosin sequences of the normal hTM_{nm} gene, including exons spliced alternatively in muscle and non-muscle tissue. Therefore, we expect that expression of the trk oncogene will be subject to the same alternative mRNA splicing rules which govern expression of the normal tropomyosin gene. The exons used in the trk transcript

exan UTT turosine kinase exon UIIIsk turosine kinase

Fig. 4 Splicing according to a non-muscle pattern (top) with fusion of exon VII to the tyrosine kinase produces the correct frame of protein translation. Splicing according to a muscle pattern (bottom) with fusion of exon VIII_{sk} to the tyrosine kinase changes the frame of translation and results in the appearance of an in-frame stop codon only five nucleotides downstream from the splice junction (arrowhead).

are those found in the 2.5-kb fibroblast mRNA except that exon VII is joined to tyrosine kinase sequences to generate the transforming protein (Fig. 4).

How would trk behave if it were expressed in muscle tissue using the exons found in the 1.3-kb muscle mRNA? Certainly the tropomyosin sequence expressed by trk would be fundamentally altered. In particular, we would expect exon VII to be joined to exon VIIIsk, as it would be in the normal muscle tropomyosin, rather than directly to the tyrosine kinase sequence. Subsequent joining of exon VIIIsk to the tyrosine kinase sequence could occur but this would change the reading frame of the trk sequence and abort the synthesis of the tyrosine kinase domain (Fig. 4). Therefore, we expect that trk will show a tissue-specific pattern of transforming activity, being active only in tissues which also express the non-muscle tropomyosin. This arises as a direct consequence of the alternative mRNA splicing mechanism which governs expression of the normal hTM_{nm} structural gene.

We thank Drs G. Modi and F. Walsh for providing samples of human muscle RNA, Mrs S. Hamilton for preparation of the typescript, and M. Barbacid and collegues for communicating their results before publication. This work was supported in part by a travel grant to F.C.R. from CNPg (20.0694/84), Brazil.

Sequences similar to the I transposable element involved in I-R hybrid dysgenesis in D. melanogaster occur in other Drosophila species

Alain Bucheton, Martine Simonelig, Chantal Vaury & Michèle Crozatier

Laboratoire de Génétique, Unité Associée au CNRS 360, Université de Clermont-Ferrand II, BP 45, 63170 Aubière, France

The I factor is a transposable element controlling the I-R system of hybrid dysgenesis in Drosophila melanogaster. This phenomenon occurs when males from the inducer class of strains are crossed with females from the reactive class of strains1. Inducer strains contain complete 5.4-kilobase (kb) I factors, reactive strains do not^{2,3}. Incomplete I elements are present in peri-centromeric regions of both categories of strains2. The 5.4-kb I factors are genetically active in stimulating hybrid dysgenesis and can transpose, whereas incomplete I elements seem to be genetically inactive and transpose rarely. The results of in situ hybridization and Southern transfer experiments indicate that most incomplete I elements are at constant locations in all D. melanogaster populations, suggesting that they were present in the genome before the spread of this species throughout the world. To investigate the evolutionary origin of the I factor, we have studied various Drosophila species for the presence of sequences homologous to it. We find that such sequences are widespread. Moreover, elements that are very similar to complete and active I factors occur in the species most closely related to D. melanogaster.

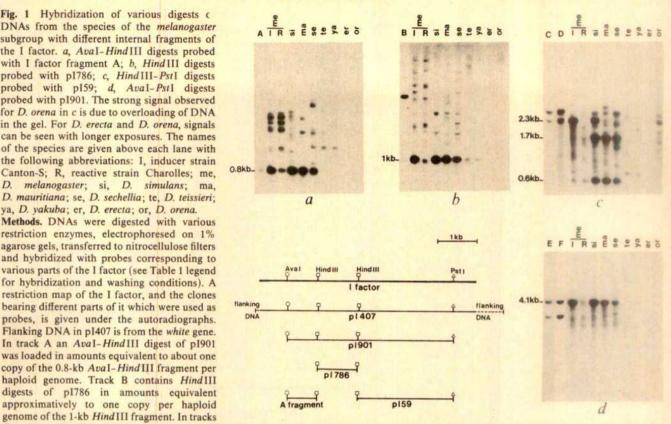

Species of the genus Drosophila have been assigned to several subgenera, the largest of which are the Sophophora and the Drosophila. D. melanogaster is a species of the subgenus Sophophora, which is divided into four groups, obscura, saltans, willistoni and melanogaster, the last one being divided in various subgroups⁴. We have studied some species of the subgenera Sophophora, Drosophila and Dorsilopha for the presence of I homologues. The results (Table 1) show that such sequences are not restricted to D. melanogaster. We have found that, except for D. takahashii, the DNAs of all the species studied in the melanogaster group show homology to the I factor. Sequences homologous with I seem to be much less frequent outside this group, for homology has been detected in only one species among eight tested in the other groups of the subgenus Sophophora and one among five in the other two subgenera. Sequences homologous to the I factor also occur in much more distant species such as Scaptomyza pallida, which belongs to another genus.

Within the melanogaster subgroup, the homology with the I factor is strongest in D. simulans, D. mauritiana and D. sechellia, weaker in D. teissieri and D. yakuba, and weaker still in D. erecta and D. orena. This correlates very well with the phylogenetic relationships between these species⁵.

Experiments were carried out to investigate the structure of the elements present in these species and to try to determine whether they are similar to the complete I factors of the inducer strains of D. melanogaster. Bucheton et al.2 have shown that restriction fragments from within the I factor are more abundant in DNA from inducer strains than from reactive strains. This is particularly true for the 2.3-kb Hind III-PstI internal fragment of I (see Fig. 1). Therefore, we used clone p159, which contains this fragment, to probe HindIII-PstI digests of genomic DNA from stocks of various species of the melanogaster subgroup.

Figure 1c shows that, as reported previously, the inducer strains of D. melanogaster contain several copies of the 2.3-kb fragment per haploid genome whereas the reactive strains do not contain it. This provides a simple means of distinguishing between reactive and inducer strains in Southern blot experiments. There is no 2.3-kb fragment hybridizing to this probe in DNA from D. erecta, D. orena, D. yakuba and D. teissieri, but the DNA from D. simulans gives a similar pattern to that obtained with the inducer strains of D. melanogaster. Indeed, this species gives a 2.3-kb fragment which hybridizes strongly to the probe as well as two smaller fragments of 1.7 and 0.6 kb. Experiments which are not reported here indicate that these smaller fragments result from the presence, in some elements, of an additional Hind III restriction site within the Hind III-PstI fragment. Very similar results are obtained with D. mauritiana and D. sechellia and in both cases many I elements have this additional Hind III restriction site.

Fig. 1 Hybridization of various digests c DNAs from the species of the melanogaster subgroup with different internal fragments of the I factor. a, AvaI-HindIII digests probed with I factor fragment A; b, Hind III digests probed with p1786; c, Hind III-Pst1 digests probed with p159; d, Ava1-Pst1 digests probed with pI901. The strong signal observed for D. orena in c is due to overloading of DNA in the gel. For D. erecta and D. orena, signals can be seen with longer exposures. The names of the species are given above each lane with the following abbreviations: I, inducer strain Canton-S; R, reactive strain Charolles; me, D. melanogaster; si, D. simulans; ma, D. mauritiana; se, D. sechellia; te, D. teissieri; ya, D. yakuba; er, D. erecta; or, D. orena. Methods. DNAs were digested with various restriction enzymes, electrophoresed on 1% agarose gels, transferred to nitrocellulose filters and hybridized with probes corresponding to various parts of the I factor (see Table 1 legend for hybridization and washing conditions). A restriction map of the I factor, and the clones bearing different parts of it which were used as probes, is given under the autoradiographs. Flanking DNA in pI407 is from the white gene. In track A an AvaI-HindIII digest of pI901 was loaded in amounts equivalent to about one copy of the 0.8-kb AvaI-Hind III fragment per haploid genome. Track B contains Hind III

C and D a HindIII-PstI digest of clone pI59 was loaded in amounts equivalent, respectively, to about one and five copies of the 2.3-kb Hind III-Pst1 fragment. Tracks E and F contain AvaI-Pst1 digests of p1901 in amounts equivalent respectively, to one and five copies per haploid genome of the 4.1-kb Ava I-Pst I fragment.

In other experiments, the same genomic DNAs were digested with AvaI and HindIII, and probed with the 0.8-kb fragment A of the I factor which had been gel purified from clone pI901 (Fig. 1a), or with Hind III and probed with clone p1786 which contains the 1-kb Hind III internal fragment of the I factor (Fig. 1b). Both of these internal fragments are present in several copies in reactive and inducer strains of D. melanogaster as well as in D. simulans, D. mauritiana and D. sechellia, but not in the other species.

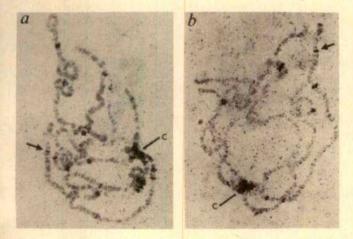

Fig. 2 Location of I factor sequences on D. simulans (a) and D. mauritiana (b). 3H-labelled pI407 was hybridized to chromosome squashes as described previously2. In each case C shows hybridization to the chromocentre. The arrow indicates region 3C, which contains the white locus. Hybridization in this region is thought to be caused by the white sequences carried by clone p1407 (see Fig. 1).

In the last Southern blot experiment, the DNAs were digested with AvaI and PstI and hybridized with clone p1901. This digestion produces a large 4.1-kb internal fragment (see Fig. 1). The results shown in Fig. 1d suggest that this large fragment is present in several copies only in the inducer strains of D. melanogaster and in the sibling species D. simulans, D. mauritiana and D. sechellia, indicating that several I homologues in these species contain most of the sequence of the complete I factor.

We have studied the distribution of I elements in the genomes of D. simulans and D. mauritiana by in situ hybridization to salivary gland chromosomes of the larvae. The results (Fig. 2) indicate that, as for the inducer strains of D. melanogaster, these sequences are present in both the peri-centromeric regions and chromosome arms of these species.

All the above results indicate that the stocks of D. simulans, D. mauritiana and D. sechellia used in these experiments differ from reactive strains of D. melanogaster and look more like the inducer strains. The sequences found in these species which are homologous to the I factor are strikingly similar to the functional I factors found in the inducer strains.

The survey of various Drosophila species reported in Table 1 indicates that I elements are an old component of the genomes and were probably present before the radiation of the melanogaster group. Many results suggest that in D. melanogaster the complete I factor appeared in natural populations in the 1930s or 1940s^{6,7}. One hypothesis advanced to explain the relationships between incomplete I elements and complete I factors is that incomplete I elements could be the result of mutational inactivation of an old transposable element, and that the complete I factor could have been formed by reactivation of some of these incomplete and defective I elements, perhaps by recombination2. Such a reactivation could have occurred in one of the four species bearing potentially active I factors-D. melanogaster, D. simulans, D. mauritiana or D. sechellia-but

DNA from various Drosophila species was prepared from adult flies and digested with restriction enzymes. The fragments were electrophoresed on agarose gels, transferred to nitrocellulose filters 14 and hybridized with clones bearing various parts of the I factor, usually p1901 and p1407 (see Fig. 1), and labelled with 32 by nick translation. to a specific activity of 3-10×10. d.p.m. per µg. Hybridization conditions were 1×Denhardt's solution (0.02% Ficell, 0.02% polyvinylpyrrolidone, 0.02% bovine serum albumin), 4×SSC, 50% formamide for at least 16 h at 37 °C. The filters were washed for 2 h in 2 × SSC, 0.1% SDS at room temperature and then for a further 2 h in 1×SSC, 0.1% SDS at 37 °C. The number of plus signs indicates the intensity of the signal observed on the autoradiographs. Most of the stocks were kindly provided by the Laboratoire de Génétique Evolutive of the CNRS at Gif-sur-Yvette (France).

it is unlikely that this occurred independently four times in each of the four species. It is more likely that the functional I factor formed only once in one species, and was then transmitted to the other three species. This could happen by horizontal transfer via an unknown vector. Another possibility resides in the fact that certain of these species can mate. The hybrids are usually sterile, but one can imagine that in such crosses some DNA sequence could be transmitted from one species to another as the result of very rare events such as polyspermy. However, the present data suggest strongly that the complete I factor was present in the ancestral species of D. melanogaster, D. simulans, D. mauritiana and D. sechellia and has been lost in D. melanogaster when this species diverged from the other three, possibly by drift. Then it could have re-invaded the D. melanogaster genome in the 1930s either by reactivation of defective I elements or by horizontal transfer from D. simulans.

The interspecific distribution of I elements is quite different from that of sequences homologous to the P factor, which is the transposable element involved in the P-M system of hybrid dysgenesis^{8,9}. Indeed, P homologues do not occur in the close relatives of D. melanogaster10 but are common in the obscura,

willistoni and saltans groups 11-13. This suggests that the two systems of hybrid dysgenesis have evolved in very different ways.

We thank Alain Pélisson for the in situ hybridization experiments shown in Fig. 2, J. C. Bregliano and D. Finnegan for criticisms of the manuscript, and J. David and D. Anxolabehere for discussions and for providing most of the stocks used in these experiments. This work has been financed by CNRS, grants UA 360 and ATP 8304, the Association pour la Recherche contre le Cancer, INSERM and Fondation pour la Recherche Médicale Française.

Cryptic simplicity in DNA is a major source of genetic variation

Diethard Tautz*, Martin Trick* & Gabriel A. Dover†

Department of Genetics, University of Cambridge, Cambridge CB2 3EH, UK

DNA regions which are composed of a single or relatively few short sequence motifs usually in tandem ('pure simple sequences') have been reported in the genomes of diverse species (for reviews see refs 1-4), and have been implicated in a range of functions including gene regulation (for reviews see refs 5-7), signals for gene conversion and recombination8-10, and the replication of telomeres¹¹. They are thought to accumulate by DNA slippage¹²⁻¹⁶ and mispairing during replication and recombination or extension of single-strand ends^{2,4,10,11}. In order to systematize the range of DNA simplicity and the genetic nature of the regions that are simple, we have undertaken an extensive computer search of the DNA sequence library of the European Molecular Biology Laboratory (EMBL)¹⁷. We show here that nearly all possible simple motifs occur 5-10 times more frequently than equivalent random motifs. Furthermore, a new computer algorithm reveals the widespread occurrence of significantly high levels of a new type of 'cryptic simplicity' in both coding and noncoding DNA. Cryptically simple regions are biased in nucleotide composition and consist of scrambled arrangements of repetitive motifs which differ within and between species. The universal existence of DNA simplicity from monotonous arrays of single motifs to variable permutations of relatively short-lived motifs suggests that ubiquitous slippage-like mechanisms are a major source of genetic variation in all regions of the genome, not predictable by the classical mutation process.

To assess the frequencies and types of simple sequence motifs, we made a systematic survey of published sequences¹⁷ using

a, The library was searched using the MATCH program³⁵ on the Cambridge IBM 3081 computer. We used 15-nucleotide (nt)-long probe sequences with matches of 13 out of 15 nt (13/15), 14 out of 15 nt (14/15) and complete matches (15/15). The actual number of matches found with each of the simple sequence probes is shown. For matching sequences longer than 15 base pairs, only one match is recorded. All possible combinations of one, two and three nucleotides were tested. In the case of the trinucleotide repeats, only one of the three possible permutations (which are indicated in the headline) was tested. The results from the runs with complementary strands and the runs with RNA probes (U instead of T) were merged. Matches with yeast mitochondrial sequences were excluded from this search because of their unusual nucleotide composition (80-90% AT). Matches due to duplicate entries of the same sequences in the library were also excluded. Testing with randomized probes was done at least four times for each nucleotide combination (two for each strand) and the values given are averages. Standard deviations are in the order of 3 for the 13/15 matches and 1 for the 14/15 matches. b, The values represent the number of matches found per 100 kb in each organism group and are therefore directly comparable. For the calculation of the proportional representation of each group of organisms, yeast mitochondrial sequences were excluded, but duplicate entries could not be excluded. It is thought, however, that this leads to an insignificant error.

two criteria. The first was to scan for direct sequence homologies to 15-nucleotide-long probes, each consisting of an array of one of all possible mono-, di- and trinucleotide motifs. Three different stringencies of homology were recorded: 13 out of 15, 14 out of 15 and 15 out of 15 bases matched. In test runs using random sequence motifs of balanced nucleotide composition, we found an average of four matches with 13/15 in the whole library (~2,100 kilobases; kb) and none with either 14/15 or 15/15. Thus, a 13/15 match could be considered as being at the borderline of significance. Controls consisted of randomized probes with equivalent nucleotide compositions.

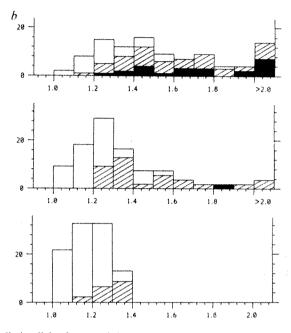

The results (Table 1; see legend for details of the tests) indicate that nearly all simple sequence motifs are considerably more

frequent than their randomized counterparts (Table 1a). The only notable exceptions are the AT/AT and GC/GC motifs. With respect to the latter, there is a known suppression of CG dinucleotides in eukaryotic nuclear DNA¹⁸. However, the level of suppression probably cannot account for the insignificant representation of this motif in simple dinucleotide repeats. Furthermore, the trinucleotide repeats composed of C and G (column CCG/CGG in Table 1a) are fairly frequent and fit into the overall frequency pattern of other trinucleotide repeats. Although it is possible that tandem arrays of GC/GC motifs are suppressed because of their potential to form Z-DNA⁵, GT/AC repeats can form the same structures and seem not to be particularly suppressed. In general, it does not seem as if

No of tetranucleotide matches: 3 (x4)= 1

Fig. 1 a, The computer algorithm. The program counts how often the oligonucleotide motif which starts to the right of each nucleotide is repeated in its direct neighbourhood. A range of parameters (motif length and window length) were tested on randomized sequences. Our actual motif and window lengths were chosen as a balance between reducing background noise and optimizing the match signal. We chose tri- and tetranucleotide motifs and a window of ±32 nucleotides. In a random sequence consisting of 25% of each nucleotide, one would expect 1 match with a trinucleotide and 1/4 match with a tetranucleotide within 64 nt. Therefore, the number of tetranucleotide matches detected are multiplied by four in the program. The final score for the respective nucleotide is then the sum from both match comparisons. This is demonstrated for the T at position 39 in the figure. The rightward trinucleotide motif from this T is TAT and the tetranucleotide motif is TATG. It is indicated which region around these is searched and where the matches were found. For six trinucleotide and three tetranucleotide matches a final score of 18 is calculated and assigned to the T at position 39. The program would then go onto the next nucleotide and repeat the cycle. Hence, each nucleotide is assigned a simplicity score. The figure also demonstrates the inbuilt correction system which eliminates double scorings due to overlapping matches. For the motif TATAT at position 43. only one match with TAT is recorded. Furthermore, the program obviates edge effects by not assigning scores to the first 32 nucleotides and the last 35 nucleotides of a sequence. The overall simplicity factor for a given sequence is calculated by summing all scores and dividing the sum by the number of nucleotides in the sequence. The relative simplicity factor is then obtained by dividing this overall simplicity factor by the overall simplicity factor obtained from 10 or 100 randomized sequences with the same nucleotide composition and a length of 10,000 nt each. Thus, the relative simplicity factor would be expected to be close to 1.0 for a sequence with no simplicity and higher for sequences with simple regions. Using 10 different

runs of randomized sequences, we can calculate a standard deviation for the overall simplicity factors of the runs and use it to assess the significance of the simplicity factor of the natural sequence. Typical results from this comparison give a significance (P < 0.01) for relative simplicity factors larger than 1.1 to 1.2. The program was written in Fortran 77 and run on the Cambridge IBM 3081 computer. b, Comparison of the frequency of simplicity factor classes between eukaryotes and prokaryotes. The histograms show the percentage of each class of simplicity factors found in sequences from eukaryotes (upper), eukaryotic cDNAs (middle) and prokaryotes (lower). All tested sequences were larger than 1 kb and were taken randomly from the EMBL library of DNA sequences (release 5). For eukaryotes, 98 different sequences were tested, 52 for eukaryotic cDNAs and 46 for prokaryotic sequences. The hatched parts of the bars represent the fraction of those sequences which contain at least one region of high simplicity. The criterion for this was that in the graphical display of the simplicity profile, at least one peak had to be higher than the line which indicates the highest peak from any of the randomized sequences of equivalent composition (the broken reference line, in Fig. 2). The filled parts of the bars represent the fraction of those sequences which contained a pure simple sequence. The criterion for this was that the sequence had to contain an uninterrupted pure simple sequence at least 15 nt long. Stretches of this length (or longer) would be expected to be detectable by direct hybridization experiments.

particular types of sequences (for example, polypurinic sequences¹⁹) are over- or under-represented.

Table 1b shows the average number of matches per 100 kb within the different species groups. The results clearly indicate that simple sequence matches are most frequent in eukaryotic nuclear genomes and very rare in prokaryotes. Chloroplasts, mitochondria and eukaryotic viruses occupy a somewhat intermediate position in this table.

In order to detect accumulations of direct oligonucleotide repeats which need not have a regular spacing (cryptic simplicity), we devised a computer program to search for such regions: Fig. 1a outlines how it works. A sequence is given an overall 'simplicity factor', which is a measure of the combined frequencies of naturally occurring, directly repeated motifs in the sequence (see Fig. 1 legend for details of the algorithm). The profile of simplicity of a given region can be displayed graphically. In addition, the program calculates a 'relative simplicity factor', which is the ratio of the simplicity factor of a test sequence to the mean simplicity factor calculated from 10 or 100 randomized sequences each consisting of 10 kb of equivalent nucleotide composition. Standard deviations were found to be very small under these conditions. The relative simplicity factor is expected to be close to 1.0 for a sequence with no cryptic simplicity, while relative simplicity factors above 1.1-1.2 are significant (P < 0.01) under our test conditions (see Fig. 1 legend).

We have tested a few hundred natural sequences with the program and found that most of them have a relative simplicity factor which is clearly higher than 1.0. As with the previous method of analysis, there is a clear difference between eukaryotic and prokaryotic sequences. The simplicity factors of the latter are clustered within a range of 1.0-1.4 (Fig. 1b, bottom), and the eukaryotic sequences are spread more evenly within a range of up to 2.0 and occasionally higher (Fig. 1b, top). Complementary DNA sequences show a somewhat intermediate position (Fig. 1b, middle), as do viral sequences (not shown). In the case of the cDNA sequences, the high simplicity regions are not only confined to the 5' or 3' untranslated regions, but can be found within the coding regions themselves (see also Fig. 2). Most of the eukaryotic sequences tested have high simplicity factors even if they do not have long arrays of pure simple sequence motifs (Fig. 1b). This implies that cryptic simplicity (the frequent occurrence of several directly repeated short motifs in close proximity) is widespread and an important component of eukaryotic genomes.

Sophisticated comparative statistics have recently been described for measuring the significance of the occurrence of repetitive motifs and other non-random properties of DNA

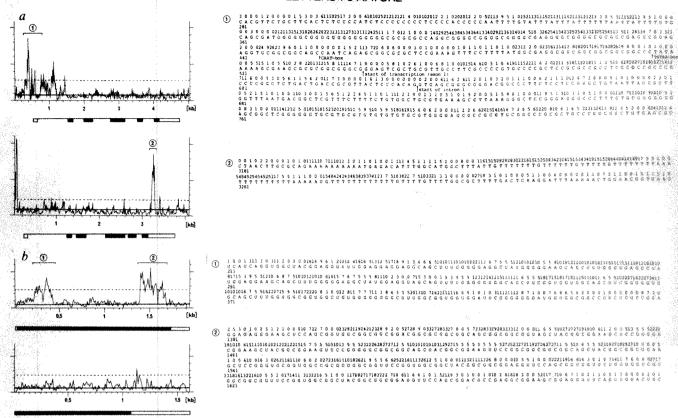

Fig. 2 Examples of high simplicity regions in eukaryotic genes. The figure shows the distribution of simple sequence regions across the genes. For this purpose, the scores from the simplicity factor calculations (averaged in 10-nt steps) are displayed in a graph above the appropriate positions in the sequence. The structure of the genes is displayed beneath the graphs. The thin line shows the length of the transcription unit, the open boxes are nontranslated parts of the mRNA and the filled boxes are the coding regions. The continuous horizontal line in the graphs is the level of the mean overall simplicity factor of 10 randomized sequences of similar composition to the test sequence. The broken line in the graphs shows the level of the highest peak in any one of the randomized sequences. Only peaks above this line are considered as high simplicity regions. Some of these were numbered and the corresponding sequences are shown to the right of the graph together with the simplicity scores found for each nucleotide. a, Upper part, chicken cytoplasmic actin gene (ref. 36, accession number in the EMBL library: X00182); lower part, rat cytoplasmic actin gene (ref. 37, accession no. V01217). b, Upper part, mouse keratin gene (cDNA) (ref. 24, accession no. V00830); lower part, human keratin gene (cDNA), the 5' end of the gene is not sequenced (ref. 38, accession no. V01516).

organization in defined sequences^{20,21}. It is satisfying that both these and our methods reveal that many (probably most) coding and noncoding sequences show significantly high numbers of short repetitive motifs, in a seemingly limitless number of permutations.

To determine whether new motifs are continually being generated on an evolutionary timescale, equivalent DNA regions were compared between species; Fig. 2 shows some characteristic examples. In the chicken cytoplasmic actin gene (Fig. 2a), a large region of simplicity composed of various different motifs stretches from a point upstream of the start of transcription and into most of the first intron. The same region in the rat gene has a far lower simplicity, even though it is also G+C-rich. Instead, there is a new high simplicity region in the 3' noncoding part of the messenger RNA which is based on oligo(T) stretches interspersed with Gs. It is unlikely that this arose by a recent integration of a retrotransposon²², because the sequences flanking it are partly conserved between chicken, rat and human and might actually be of functional significance²³. The large peak in front of the rat gene is also due to an oligo(T) stretch.

Figure 2b shows cryptic simple sequences in the coding sequences of the rat keratin gene. There are two glycine-rich regions which are highly divergent between the keratin genes, while the body of the gene, which our analysis indicates is not simple, is fairly strongly conserved, even between different types of intermediate filaments²⁴. The human keratin gene is much less simple in the equivalent regions (only part of the human gene sequence is known).

It has been noted previously that some regions of mammalian 28S ribosomal RNA genes are highly divergent in close species comparisons²⁵. Detailed examination of the distribution of cryptic simplicity in mouse and rat 28S rDNA shows that they coincide exactly and in very great detail with the regions of divergence in the two genes as depicted by standard dot matrices (Fig. 3). The regions in question are known to be insertions (when compared with other eukaryotic rRNA genes), probably originating by slippage-like mechanisms and not by the drift of point mutations in neutral sequences that were once shared by all species.

Our results show that there is a significantly frequent occurrence of nearly all possible short simple sequence motifs in natural DNA sequences in both coding and noncoding regions of eukaryotic genomes. There must be a mechanism active throughout most of the genome which can create simplicity, and which acts largely independently of the actual sequences involved. It is reasonable to assume that this mechanism is slippage. It is known that short oligonucleotide motifs can slip easily against each other⁷, for this is a very efficient way to produce simple sequence DNA in vitro 14,15. From direct comparisons of closely related natural DNA sequences, it is clear that slippage can also occur in vivo between short direct repeats, leading to deletions or expansions of the motifs involved (for examples see refs 4, 10, 12, 13, 16, 26-28).

The apparent under-representation of simplicity in prokaryotes is probably not due to the absence of such mechanisms, but merely to the more economical use of DNA in these

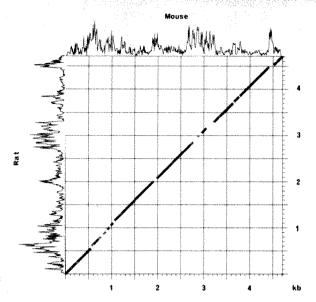

Fig. 3 Comparison of the genes for the 28S ribosomal RNA from mouse to rat. The figure shows a standard dot matrix plot between mouse³⁹ and rat⁴⁰ 28S rRNA genes. Match stringency was 20 nt perfect match. The plot is superimposed with the simplicity profiles of these genes, with the mouse gene on the upper axis and the rat on the left axis.

organisms, for they have low amounts of noncoding spacer DNA. Interestingly, prokaryotes also have a more frequent occurrence of simple trinucleotide motifs (compare Table 1), possibly due to their tolerance by the triplet code.

Two broad categories of simplicity can be distinguished—pure simple sequence regions and regions of less regularity but with a clear bias in nucleotide composition (compare Fig. 2). Ohno has suggested that the latter regions, where they occur within genes, might be the remnants of the former, which gradually diverged with the accumulation of point mutations²⁹. However, it is inconceivable that random point mutations within a simple sequence could by itself lead to the observed biases in nucleotide composition and to scrambling of new and old motifs. The observations can be more easily explained in terms of an interaction between point mutations and continual slippage.

The turnover of simple motifs could make some contribution to the observed differences in codon usage between genes and species, and in the potential of chromatin to undergo conformational changes and bind to regulatory proteins associated with gene transcription. Furthermore, it seems unlikely that substantial amounts of complex 'single-copy' DNA exist which are diverging in a clock-like manner, given that most DNA is subject to one or other turnover mechanism^{30,41}.

Mechanisms of continuous gain and loss of DNA variants by unequal crossing over and gene conversion can lead to the homogenization (molecular drive) of any given variant in a sexual population^{30-33,41}. No large-scale homogenization is occurring by gain and loss due to slippage because our survey shows that the unit of slippage can occasionally be out of phase with pre-existing motifs. Thus, any homogenization is continually being obliterated by the generation and combinatorial reshuffling of short and short-lived motifs differing in sequence and length. The effects on the overall genetic composition of a population and any interaction with selection are probably complex^{4,30,34,41}. It appears that the genetic material acquires its new forms more as a consequence of novel combinations between simple units than by the point-by-point substitutions of one base by another in a passive DNA molecule.

Nuclear factor III, a novel sequence-specific DNA-binding protein from HeLa cells stimulating adenovirus DNA replication

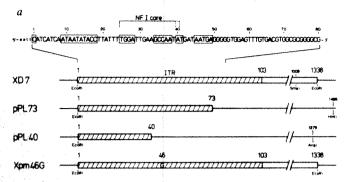

Ger J. M. Pruijn, Wim van Driel & Peter C. van der Vliet

Laboratory for Physiological Chemistry, State University of Utrecht, Vondellaan 24 a, 3521 GG Utrecht, The Netherlands

Dissection and reconstitution of the adenovirus DNA replication machinery has led to the discovery of two HeLa nuclear proteins which are required in conjunction with three viral proteins 1-4. One of these, nuclear factor I (NF-I), recognizes an internal region of the origin between nucleotides 25 and 40 (refs 4-8) and by binding to one side of the helix stimulates the initiation reaction up to 30-fold. NFI-binding sites have been observed upstream of several cellular genes, such as chicken lysozyme^{9,10}, human IgM¹¹ and human c-myc12, and coincide in most cases with DNase I hypersensitive regions. Here we report the identification of a novel DNA-binding protein from HeLa nuclei, designated NF-III, that recognizes a sequence in the adenovirus origin very close to the NFI-binding site, between nucleotides 36 and 54. This sequence includes the partially conserved nucleotides TATGATAATGAG. NF-III stimulates DNA replication four- to sixfold by increasing the initiation efficiency. Potential cellular binding sites include promoter elements of the histone H2B gene, the human interferon β gene, the human and mouse immunoglobulin V_{κ} and $V_{\rm H}$ genes and the mammal/chicken/Xenopus laevis U1 and U2 small nuclear RNA genes. Furthermore, a subset of the herpes simplex virus immediate early promoter specific TAATGARAT elements is homologous with the adenovirus 2 (Ad-2) NFIII-binding site.

Replication of adenovirus DNA in human cells occurs by a protein-priming mechanism in which a precursor to the viral terminal protein (pTP) becomes covalently bound to the first nucleotide, a dCMP residue. The 3'-OH group of dCMP in this

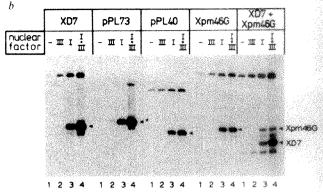

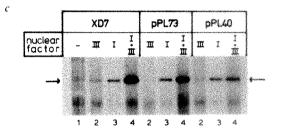

Fig. 1 Template-dependent stimulation of adenovirus DNA replication in vitro by NF-III. a, DNA sequence of part of the Ad-2 ITR containing the origin region and structure of the mutants. The C at position 1 is the left terminal nucleotide of the Ad-2 ITR (top strand). Sequences conserved between the various human adenovirus serotypes are boxed. The core of the NFI binding site extends from position 25 to 39 or 40 as indicated. The adenovirus inserts in the plasmids are indicated by bars, ITR sequences by hatched bars. Relevant restriction sites are marked. b, In vitro replication of fragments containing terminal Ad-2 DNA sequences. Appropriate plasmid digests were incubated with purified viral replication proteins under the conditions described below, in the absence of nuclear proteins (lane 1) or in the presence of NF-III (lane 2), NF-I (lane 3) or a combination of both proteins (lane 4). The reaction products were separated by agarose gel electrophoresis in the presence of 0.1% SDS followed by autoradiography. As a consequence of the protein priming mechanism, newly replicated DNA fragments are covalently coupled to the precursor to the terminal protein (pTP) leading to a shift in mobility. Replicated fragments are indicated by arrowheads. c, Initiation of adenovirus DNA replication stimulated by NF-III. A

digest of XD7, pPL73 or pPL40 was incubated as described in b, but in the presence of $[\alpha^{-32}P]dCTP$ as the only nucleotide triphosphate. The products were analysed for the formation of the pTP-dCMP initiation product by SDS-polyacrylamide gel electrophoresis and autoradiography. The arrow indicates the position of pTP-dCMP.

Methods. The constructions of XD7 (ref. 28), pPL73 (ref. 17), pPL40 (ref. 7), and Xpm46G (ref. 8) have been described. XD7 was digested with EcoRI, pPL73 with EcoRI and HinfI, pPL40 with EcoRI and AvaI and Xpm46G with EcoRI, while for the replication of a mixture of XD7 and Xpm46G, XD7 was also digested with SmaI. DNA replication assays were performed in a final volume of 15 μ l containing 25 mM Hepes-KOH (pH 7.5), 4 mM MgCl₂, 0.4 mM DTT, 1.7 mM ATP, 5 mM creatine phosphate, 5 μ g ml⁻¹ creatine kinase, 17 μ M each of dATP, dGTP and dTTP, 2 μ M [α -²P]dCTP (25 Ci mmol⁻¹), 2 mU pTP-adenovirus DNA polymerase complex, 1.25 µg adenovirus DNA-binding protein, 1 µl HeLa cytosol, 0.6 mM aphidicolin, 30 ng XD7 or 14 ng pPL73 or 22 ng pPL40 or 30 ng Xpm46G or 15 ng XD7 and 15 ng Xpm46G and 1 μl NF-I or NF-III when indicated. The amounts of plasmid DNA were chosen to obtain identical concentrations of origin fragments. Reaction mixtures were incubated for 60 min at 37 °C. When assaying initiation dATP, dGTP and dTTP were omitted. The purification of pTP-DNA polymerase. DNA-binding protein of cytosol and NF-I has been described. For NF-I hydroxylapatite fractions were used. NF-III was purified as follows. Nuclei from 10 HeLa cells were isolated and washed three times with 25 mM Tris-HCl (pH 7.5), 10% sucrose, 1 mM phenylmethylsulphonyl fluoride (PMSF) and 20 µg ml⁻¹ L-1-tosylamide-2-phenyl-ethylchloromethyl ketone (TPCK). The nuclei were suspended in the same buffer containing 1 mM EDTA and 1 mM dithiothreitol (DTT). Nuclear proteins were extracted by addition of 5 M NaCl to 0.3 M final concentration and slow stirring at 0 °C for 30 min. Cellular debris was removed by successive centrifugations at 12,000 g for 20 min and 105,000 g for 40 min. The final supernatant was adjusted to 0.2 M NaCl by addition of buffer A (25 mM Tris-HCl (pH7.5), 1 mM EDTA, 1 mM DTT, 1 mM PMSF, 20 µg ml⁻¹ TPCK, 20% glycerol) and applied to a DEAE-cellulose column equilibrated with buffer A containing 0.2 M NaCl. The flow-through was dialysed against buffer B (25 mM Tris-HCl pH 7.5), 1 mM EDTA, 1 mM DTT, 1 mM PMSF, 20 µg ml⁻¹ TPCK, 20% glycerol, 10% sucrose, 0.01% Nonidet P40) containing 0.03 M NaCl and applied to a second DEAE-cellulose column equilibrated with buffer B containing 0.03 M NaCl. The column was washed with buffer B-0.03 M NaCl and eluted with a linear gradient of 0.03-0.3 M NaCl in buffer B. The peak of NF-III activity was present in the first wash fractions following the flow-through. These fractions were applied to a phosphocellulose column equilibrated with buffer B-0.03 M NaCl. Bound material was eluted with a linear gradient of 0.03-1 M NaCl in buffer B. NF-III activity eluted at 0.15 M NaCl. NF-III-containing fractions were combined, adjusted to 0.05 M NaCl by addition of buffer B and applied to a denatured DNA-cellulose column equilibrated with buffer B-0.05 M NaCl Bound material was eluted with a linear gradient of 0.05-1 M NaCl in buffer B. NF-III activity eluted at 0.24 M NaCl. All purification steps were performed on ice or at 4°C. Throughout the purification, NF-III activity was monitored by its ability to stimulate the replication of the origin containing 6146 and 5641 bp XhoI B and C fragments, respectively, obtained from the Ad-5 DNA-TP complex 14.

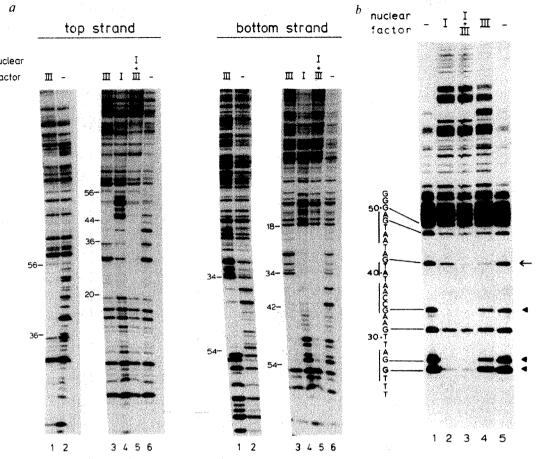

pTP-dCMP complex serves as a primer for further polymerization by a strand displacement mechanism (for reviews, see refs 1, 2, 13). Both initiation and elongation can be accomplished in vitro using five purified proteins. Three of these are encoded by the virus: the single-strand DNA-binding protein (DBP). DNA polymerase (pol) and pTP. The remaining proteins, NF-I and-II, are purified from HeLa nuclei3,4. Previously we observed that sera from patients suffering from various autoimmune diseases inhibit adenovirus DNA replication in vitro 14. This inhibition was only observed when crude HeLa nuclear extracts were used, but not in the presence of purified NF-I. As NF-II was not required in the assay, this suggested the existence of additional HeLa proteins required for optimal replication. Therefore, we searched directly for such proteins using a replication assay containing DBP, pTP, pol and NF-I. HeLa nuclei were extracted with 0.3 M NaCl and the extract was fractionated on DEAEcellulose. Screening of the column fractions revealed the presence of a new protein that stimulated replication four- to sixfold. This protein, NF-III, eluted at 30 mM NaCl whereas NF-I eluted at 80 mM NaCl. NF-III was further purified by phosphocellulose and denatured DNA cellulose chromatography. The

stimulatory activity of NF-III was sensitive to 0.1 mM N-ethylmaleimide and was 90% inactivated by heat treatment for 15 min at 50 °C.

To determine whether specific regions of the Ad-2 inverted terminal repeat (ITR) were required for stimulation by NF-III we used plasmid DNA containing either the wild-type origin (XD7) or several mutant origins. Origin-containing plasmid DNA can replicate in vitro provided that the DNA is linearized at the origin ^{15,16}. Protein-primed replication is visualized by a shift in electrophoretic mobility of the origin fragment caused by covalent binding of the pTP to the synthesized DNA. The plasmids pPL73 and pPL40 contain the terminal 73 and 40 base pairs (bp) of the Ad-2 ITR, respectively (Fig. 1a). Xpm46G is a derivative of XD7 with an $^{\Lambda}_{-} \rightarrow ^{C}_{G}$ transition at position 46.

Replication of all these mutants was stimulated by NF-I similar to wild type (Fig. 1b) in accordance with previous results 7.8.17. However, only wild-type XD7 and pPL73 were stimulated by NF-III, whereas pPL40 and Xpm46G were not. Similar results were obtained when the initiation reaction (pTP-dCMP synthesis) was studied (Fig. 1c). This indicates that NF-III, like NF-I, exerts its effect on the level of initiation. But

Localization of the NF-III binding site in the Ad-2 ITR. a, DNase I footprint analysis of NF-III- and NF-Ibinding sites in the Ad-2 ITR. The figure shows autoradio- nuclear graphic exposures of 10% polyacrylamide sequencing gels used to analyse the partial DNase I digests of end-labelled Ad-2 origincontaining DNA fragments. Lanes 2 and 6 show control DNase digestion patterns in the absence of nuclear protein fractions. Lanes 1 and 3 show the DNase cleavage pattern in the presence of NF-III. The remaining lanes show the DNase digestion patterns in the presence of NFI (lane 4) or both NFI and NFIII (lane 5). Numbers, positions in the Ad-2 ITR as in Fig. 1a, which were determined using Gtracks and specific restriction fragments as markers. b, Methylation protection analysis of NF-III and NF-I binding sites in the Ad-2 ITR. Autoradiographic exposure of a 10% polyacrylamide sequencing gel used to analyse the partially methylated endlabelled Ad2 origin containing DNA fragments after cleavage by piperidine treatment. Lanes 1 and 5 show control methylation patterns in the absence of nuclear protein fractions. Lanes 2 and 4 show pattern

obtained in the presence of NF-I and NF-III, respectively, while lane 3 shows the methylation pattern obtained in the presence of both NF-I and NF-III. The sequence at the left of the autoradiogram shows part of the Ad-2 ITR (top strand) and indicates the position of primary methylation sites. The G-residue protected by NF-III is indicated with an arrow, while residues protected by NF-I are indicated by arrowheads.

Methods. The footprint and methylation protection probes were constructed as follows: To the single-stranded M13 clones MXE-1 and MXE-4, 5' end-labelled synthetic oligonucleotides were hybridized. MXE-1 (ref. 8) and MXE-4 contain the top strand and the bottom strand of the EcoRI fragment of XD7, respectively. For top strand analyses the oligonucleotide was complementary to a M13 sequence in MXE-4 ranging from position -21 to -5 relative to position 1 of the Ad-2 insert. For bottom strand analyses the oligonucleotide was complementary to the Ad-2 sequence in MXE-1 ranging from position 65 to 81 of the Ad-2 insert. After hybridization the oligonucleotide primers were elongated with Klenow DNA polymerase giving the double-stranded constructs containing the Ad2 origin, 5' end-labelled at either the top (position -21) or the bottom strand (position 81). These constructs were incubated with 15 μl NF-III (denatured DNA-cellulose fraction, see legend to Fig. 1) and/or 10 μl NF-I (hydroxyl apatite fraction) in a total volume of 75 μl containing 25 mM Hepes-NaOH (pH 7.5), 1 mM DTT, 0.5 mM MgCl₂, 50 mM NaCl, 50 ng pBR322, and 5 μg bovine serum albumin for 60 min at 0 °C. For DNase I footprints 5 μl 50 mM MgCl₂ and 0.1 U DNase I were added. Digestion was allowed for 90 s at 24 °C and stopped by addition of 4 μl 0.2 M EDTA, 10% SDS. For methylation protection analyses 200 μl sodium acetate, 50 mM, 1 M β-mercaptoethanol. After ethanol precipitation the DNA was dissolved in 100 μl 1 M piperidine, incubated at 90 °C for 30 min and analysed as described above.

stimulation by NF-III is dependent on the presence of sequences between 40 and 73, outside the recognition sequence of NF-I. Furthermore, a point mutation at position 46, located in a highly conserved pentanucleotide sequence ⁴⁵AATGA⁴⁹, completely prevents stimulation by NF-III. This suggests that NF-III acts by binding to sequences between 40 and 73 including ⁴⁵AATGA⁴⁹. Specific binding to origin fragments could indeed be demonstrated using a nitrocellulose-filter binding assay or an exonuclease III protection assay (data not shown).

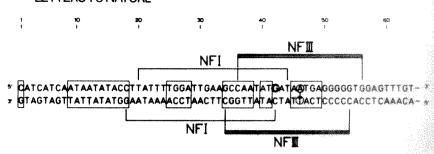

To identify the sequences involved in binding, we determined the region of the Ad-2 ITR that is protected against DNase I by footprint analysis. The Ad-2 origin containing region of the single-stranded M13 clones MXE-1 and MXE-4 were converted to double-stranded DNA by hybridization to 5' end-labelled synthetic oligonucleotides and elongation of these oligonucleotides using Klenow DNA polymerase. These constructs were partially digested with DNase I in the presence or the absence of NF-III (Fig. 2a, lanes 1, 2). NF-III protected the region between positions 36 and 56 of the top strand and the region between positions 34 and 54 of the bottom strand. Figure 2a also shows that the NF-III footprint partially overlaps the NF-I footprint (Fig. 2a, lanes 3, 4) and that mixtures of NF-I and NF-III protected the combined regions (Fig. 2a, lane 5). This

indicates that NF-I and NF-III can simultaneously bind to their recognition sequence and do not exclude each other.

Methylation protection experiments were performed to analyse possible contact points between NF-I and NF-III and their recognition sequence (Fig. 2b). NF-I protected G-residues at positions 26, 27 and 34 in the top strand from methylation by dimethylsulphate, whereas NF-III protected only the G-residue at position 42. Surprisingly, the conserved G-residue at position 48 was not a contact point. As guanosines are methylated at the N⁷ position located in the major groove this suggests that, like NF-I, NF-III binds at least in part in the major groove of the DNA helix. Mixtures of NF-III and NF-I protected all four G-residues (Fig. 2b, lane 3) confirming that NF-I and NF-III can simultaneously bind to their recognition sequence.

The results are summarized in Fig. 3. The DNase I footprint of NF-III partially overlaps both the NF-I footprint and the NF-I core recognition sequence (Fig. 1a). This close spacing of the two proteins is remarkable. Using extensive contact point analysis we have recently shown that NF-I binds to one side of the helix (E. de Vries et al., in preparation). The presence of a contact point between NF-III and a G-residue at position 42, only 6 bp removed from a contact point between NF-I and a G-residue at position 36, suggests that NF-III could bind at

Fig. 3 NF-III binding site in the adenovirus-2 origin. Highly conserved nucleotides within the terminal part of the Ad-2 ITR are boxed. Large brackets indicate the regions of both strands that are protected against DNase I digestion by either NF-I or NF-III. Circles, the G-residue protected against methylation by NF-III binding and the AT base pair essential for NF-III stimulation of replication.

least in part at the opposite side of the double helix compared to NF-I. At present we do not know whether the two proteins interact physically at their binding site. So far, we have not observed protein-protein interactions in solution between NF-I and NF-III during purification, comparable to, for example, the pTP-pol complex

The region protected by NF-III contains in its centre the sequence ³⁹TATGATAATGAG⁵⁰, much of which is conserved among the human and simian adenoviruses. A computer search reveals several homologous sequences in cellular DNA. A striking similarity was found with a promoter element of histone H2B genes, the H2B-specific homology block GTATGCAAATGAG, located close to the TATA box¹⁹. Several conserved promoter elements of other genes display similar homologous sequences. These genes include the human and mouse immunoglobulin V_{κ} and $V_{\rm H}$ genes²⁰ (consensus ATGCAAATNA, ~100 nucleotides upstream of the start of the coding region), the human interferon β (ATGTAAATGA, about 100 nucleotides upstream of the transcription start site) and the mammal/chicken/Xenopus laevis U1 and U2 snRNA genes^{22,23} (consensus PyATGPyAPuATG located 250-220 nucleotides upstream from the 5' terminus of mature RNA). Furthermore, some TAATGARAT elements of the herpes simplex virus immediate early promoters²⁴ are highly homologous with the Ad-2 NF-III-binding site (consensus PuPyGNTAATGAPuATNC). It would be interesting to see whether NF-III binds to any of these regulatory elements.

The requirement for a functional NF-I site for adenovirus DNA replication in vivo has been established^{25,26}, but the role of NF-III is unclear. Plasmids containing either nucleotides 1-45 or 1-67 are reported to be fully active in replication in vivo^{25,26}. Interestingly, replication-competent Ad-4 DNA which lacks a functional NF-I site²⁷ binds NF-III efficiently in filter binding assays (G.J.M.P., A.M.A.A. Kavelaars, and P.C. van der V., unpublished observations). Recently, we were informed that a protein with similar properties to NF-III has been found by P. J. Rosenfeld and T. J. Kelly (personal communication).

Since submission of this manuscript, in collaboration with Drs G. Tebb, D. Bohmann and I. W. Mattaj (EMBL, Heidelberg) we have shown by footprint analysis that NF-III binds well to the Xenopus laevis U2 upstream conserved sequence (-269 to -259). This sequence is required for efficient transcription of U2 snRNA genes (D. Bohmann, T. Dale, G. Tebb, H. R. Schöler, I. W. Mattaj & W. Keller, in preparation) suggesting that NF-III can function both in DNA replication and transcription.

We thank Drs E. de Vries, P. A. J. Leegwater and R. T. Hay for providing mutants. This work was supported in part by The Netherlands Foundation for Chemical Research and The Netherlands Organization for the Advancement of Pure Research.

Green light-mediated photomorphogenesis in a dinoflagellate resting cyst

Brian J. Binder & Donald M. Anderson

Department of Biology, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

Developmental responses to light are well known and ubiquitous among higher plants1, but examples of such responses among the algae are less common. Those responses which have been reported in this group are generally photoperiodic or require prolonged light exposures; most involve macrophytes2. We now report a non-photosynthetic, low-threshold, photomorphogenic response in a unicellular alga, the dinoflagellate Scrippsiella trochoidea (Stein) Loeblich. In contrast to the reported behaviour of most other dinoflagellate species, resting cysts of S. trochoidea require light to germinate. This requirement is satisfied to a large extent by low photon fluences delivered in exposures as short as I second. Green light is most effective in eliciting the response. Given the importance of dinoflagellates as primary producers in many aquatic ecosystems and the potential role of resting cysts in controlling the dynamics of natural dinoflagellate populations, the present observations are of obvious ecological significance. The primitive phylogenetic standing of dinoflagellates³, and the relative rarity of green light-mediated photomorphogenic responses in eukaryotes generally 4,5, suggest that this phenomenon may also hold considerable evolutionary and photophysiological interest.

Temperature has been almost universally cited as the environmental factor exerting primary control over germination in dinoflagellate resting cysts^{6,7}. When considered, light conditions have generally been found to exert little effect on cyst germination 8-11

In the two studies to date which have demonstrated a light effect, germination was delayed but not prevented by darkness^{12,13}. Preliminary studies with *S. trochoidea* have confirmed that temperature is important in controlling germination in cysts of this species, but have also demonstrated that germination may be significantly reduced in the absence of light¹⁴. The present study was undertaken to elucidate the influence of light on germination in cysts of *S. trochoidea*.

Scrippsiella trochoidea is a small photosynthetic marine dinoflagellate of widespread neritic distribution. Cysts for the present study were produced in axenic clonal cultures (clone SA10, from Perch Pond, Falmouth, Massachusetts) under a 14:10 h daily light: dark (L:D) cycle at 18 °C¹⁴. Within a week of the appearance of cysts, the cultures were enriched with inorganic nutrients at f/2 levels¹⁵ and placed in darkness at 3 or 18 °C. Every precaution was taken to insure that no further light reached these cultures. Sampling and manipulations, when necessary, were carried out in total darkness.

Under these strictly dark conditions, cysts stored at 18 °C failed to germinate over the 120 days of the experiment, although conditions should otherwise have been optimal for excystment (Fig. 1). Exposure of these cysts to the standard 14:10 h L:D cycle (\sim 650 μ mol photons m⁻² s⁻¹), at the same temperature,

resulted in rapid germination.

An upward shift in temperature commonly results in rapid and complete germination of dinoflagellate cysts which have been stored at low temperature (Fig. 1)^{6,7}. In the present case, however, no germination occurred among cysts so treated if they were deprived of all light (Fig. 2). In contrast, cysts exposed to as little as 2 min of light germinated rapidly and only slightly less successfully (though significantly so) than those exposed to the same level of illumination for 14 h daily (P < 0.001). The response to 60 min of light was indistinguishable from that in the 2-min treatment.

The relationship between total 'white light' photon fluence and germination underscores the sensitivity of S. trochoidea cysts to low levels of light (Fig. 3). A 50% response (based on a maximum achieved germination frequency of 60%) occurs in these cysts at approximately 0.2 μ mol m⁻² photon fluence. This photon fluence corresponds to an exposure time at standard culturing irradiances (see above) of far less than 1 s.

The germination response appears to be dependent upon photon fluence (μ mol m⁻²), rather than fluence rate (μ mol m⁻² s⁻¹) or exposure time separately. Thus, equivalent germination is elicited by equal photon fluences, whether applied over 10 or 1,000 s (Fig. 4).

These results clearly demonstrate that light is required for germination in S. trochoidea cysts. Furthermore, the fact that a low-irradiance exposure lasting 1s is sufficient to stimulate germination raises the possibility that previous studies with dinoflagellate cysts (including our own), designed primarily with longer-term light effects in mind, may have been unable to distinguish between such a low threshold response and true

'dark' germination.

The response by S. trochoidea cysts to the same photon fluence (0.12 \(\mu\text{mol m}^{-2}\)) at different wavelengths is shown in Fig. 4. Germination is maximal in the 550-nm (yellow-green) band, with wavelengths above 620 nm being ineffective at this fluence level. The response drops more slowly on the low side of 550 nm, and is still apparent in the blue (450 nm) band. There was no evidence of modification of the 550-nm band response by subsequent exposure to red or far-red light (650 ± 20 nm or 750 ± 20 nm) at equivalent fluence levels (data not shown). The relatively low germination frequency among all the wavelength-band treatments is consistent with the low response achieved in the white-light controls of this experiment (Fig. 4) and therefore cannot be taken to indicate a low response to monochromatic light generally. The cause of the reduced germination in this experiment is not known, but the pattern of response to different wavelength bands was confirmed by preliminary experiments

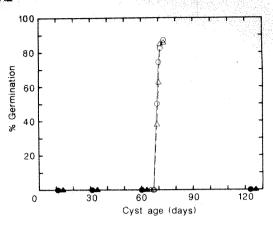

Fig. 1 Germination of S. trochoidea cysts placed in the dark at 3 °C (♠) or 18 °C (♠) starting at age 7 days. On day 65, some cysts from both the 3 °C and 18 °C dark storage (○, △, respectively) were placed under a continuing 14:10 h L:D cycle at 18 °C.

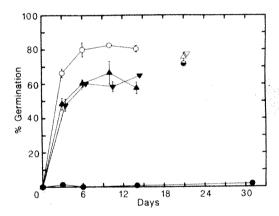

Fig. 2 Time course of germination by cysts (stored at 3 °C in the dark) on transfer to 18 °C and exposure to a continuing 14:10 h L:D cycle (\bigcirc), to 60 min of light only (\blacktriangledown), to 2 min of light (\blacktriangle), and to no light (\spadesuit). On day 14, cysts from the three latter treatments were exposed to the continuing 14:10 h L:D cycle and assessed 6 days later (\triangledown , \triangle , \Longrightarrow , respectively); means ± 1 s.e. (n = 2).

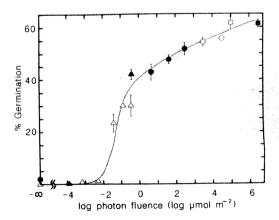

Fig. 3 Effect of 'white light' photon fluence $(\mu \text{mol m}^{-2})$ on germination frequency. Incandescent source, except \square and \blacksquare (which are taken from Fig. 2), illuminated with a cool white fluorescent source. Photon fluence is the product of exposure time and fluence rate [measured for photosynthetically active wavelengths only $(400 \text{ nm} < \lambda < 700 \text{ nm})$ with a scalar irradiance meter (Biospherical Instruments, Inc.) and adjusted, as necessary, with neutral density filters]. Exposure times are \triangle , 1 s; \triangle , 5 s; \bigcirc , 12 s; \square , \bigcirc , 120 s; \blacksquare , 3,600 s; means \pm 1 s.e. (n=3), except n=6 for \square and \blacksquare). Line drawn by eye.

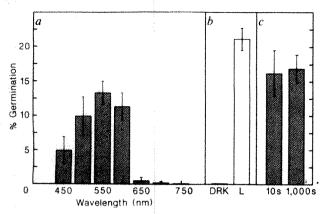

Fig. 4 Germination response of S. trochoidea cysts to wavelength. a, Bars show the frequency of germination achieved in cysts exposed to equal photon fluences ($\sim 0.12 \,\mu\text{mol m}^{-2}$) in seven different wavelength bands. Incandescent source, in combination with wide-band interference filters (40 nm half-power bandwidth, blocking outside of band better than 0.1% between low ultraviolet and 1,000 nm; Ditric Optics Inc.). Exposure time was 10 s in all cases; fluence rate was adjusted with neutral density filters and by varying source voltage; means ± 1 s.e. (n = 3); bar width represents half-power bandwidth, on wavelength scale shown. b. Open bar is the 'white light' control; unfiltered incandescent source, 4.2 umol m^{-2} (corresponding to $\sim 0.5 \, \mu \text{mol m}^{-2}$ in the $550 \pm 20 \, \text{nm}$ band). DRK bar, the dark control. c, Germination response to approximately equivalent photon fluences ($\sim 1 \, \mu \text{mol m}^{-2}$, $\lambda = 550 \pm 20 \, \text{nm}$) administered over 10 s or 1,000 s, as indicated.

which, however, involved less complete coverage of the spectrum.

Overall, our data indicate that the response to light in S. trochoidea cysts is not photosynthetic. This conclusion is based on the low photon fluence requirement of the response and its relative sensitivity to green light as compared with blue or red. The conclusion is further supported by the inability of darkstored S. trochoidea cysts to photosynthesize immediately after their transfer to light¹⁴.

Other non-photosynthetic responses to light which have been reported in dinoflagellates include phototaxis 16-18 and growth inhibition by far-red exposures 19. Generally, green wavelengths are not active in these phenomena; the photoreceptor systems responsible are therefore probably different from that involved in the light-triggered germination of S. trochoidea cysts.

Among algal resting stages generally, germination of cyanobacterial akinetes²⁰⁻²² and diatom resting spores^{23,24} has been widely found to be light-dependent. In contrast to the present case, the response in akinetes is maximal in the red wavelengths and generally requires extended exposures (hours to days) and high photon fluences^{21,25}. Similarly, diatom resting spores are responsive only to relatively high fluence rates²³. In neither of these cases can photosynthetic involvement be confidently discounted.

The extent to which the unique light requirement described here could control the germination of S. trochoidea cysts in the natural system depends on several factors, including the optical properties of overlying waters (note that coastal waters generally transmit maximally in the green band), the extent to which reciprocity in the response holds (that is, the maximum time over which 'photon counting' can occur), and the influence of cyst age and environmental parameters on the response itself. Preliminary calculations, based on conservative assumptions about these factors (including a maximum photon counting time of 1,000 s), indicate that in average coastal waters of moderate depth (~40-80 m) significant germination will occur, although the germination frequency ultimately achieved could be light limited14. On the other hand, in particularly deep or turbid waters, light could be sufficiently attenuated to prevent germination completely. Furthermore, the burial of cysts in the sediment

would probably result in prohibitively low light levels regardless of the depth of the overlying water column. In these latter cases, resuspension from the sediment surface and/or advection to shallower depths would presumably be required before significant germination could occur.

Although the ecological consequences of light-triggered germination in S. trochoidea cannot be fully appraised without further information on the physiology of the response, it is clear that light can no longer be ignored in considerations of the behaviour of dinoflagellate cysts in the natural system.

The crystal structure of d(GGATGGGAG) forms an essential part of the binding site for transcription factor IIIA

Maxine McCall, Tom Brown*, William N. Hunter & Olga Kennard

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, UK

Most genes in higher organisms are activated by the binding of proteins called transcription factors. One such protein, transcription factor IIIA (TFIIIA) from the frog, activates the gene for 58 RNA by binding to the region of the gene between nucleotides 45 and 97. This binding site has been defined by a variety of blochemical studies, including base-deletion experiments and DNase I footprinting1. The protein also binds to the gene product: in immature frogs it is stored as a complex with 5S RNA. From the observation that TFIIIA can bind to either double-helical DNA or RNA, and from their own measurements, Rhodes and Klug have proposed that the DNA-binding site for TFIIIA has an RNA-like structure. Here we present the crystal structure analysis of a part of the DNA-binding site (nucleotides 81-89 of the gene)

^{*} Present address: Department of Chemistry, University of Edinburgh, Edinburgh 1849 347, 136

which forms a particularly strong interaction with the protein, and show that it has a conformation similar to the A' form of doublehelical RNA.

Miller et al.3 have shown recently that the amino-acid sequence of TFIIIA contains multiple repeats of a 30-residue unit which they called a 'finger'. There are nine such fingers in the 344-residue TFIIIA, each of which contains the sequence Cys...Cys.... His.. His and is thought to complex a zinc ion. Finger sequences have now been found in at least four other DNA-binding proteins from higher organisms^{2,4-6}, suggesting that this structural unit is of primary importance in many cell processes. It is not known definitively how much DNA each finger covers but assuming that there is one TFIIIA protein bound per 50 base pairs (bp) of DNA7, each finger would have to recognize about 5.5 bp, or one-half of a double-helical turn. Indeed. Rhodes and Klug2 have recently provided evidence for a structural repeat of 5.7 bp in the TFIIIA binding site, to match the required amount of DNA per finger. At the suggestion of Dr A. Klug we have investigated the three-dimensional structure of part of the gene for 5S RNA by single-crystal X-ray diffraction methods. Nucleotides 81-89 of the gene were chosen because, as shown by methylation interference8, methylation protection9 and base deletion experiments 10,11, this stretch of DNA is more important for the binding of TFIIIA than any other part. The base sequence of our selected molecule, and its relation to the length of DNA covered by TFIIIA, are shown in Fig. 1.

The two strands d(GGATGGGAG) and d(CTCCCATCC) were synthesized by the triester method¹² and purified separately. They were then mixed in equimolar proportions, as calculated from their respective ultraviolet absorbances at 260 nm, to form a double helix of relative molecular mass 5,500. Crystals were grown by vapour diffusion against 6-20% 2-methyl-2,4pentanediol (MPD) from a mixture which initially contained 0.2 mM DNA, 12 mM magnesium acetate, 12 mM sodium cacodylate (pH 6.5) and 0.8 mM spermine HCl. The crystals grew as tetragonal rods to a size of $0.5 \times 0.18 \times 0.18 \text{ mm}^3$ during 5 months at room temperature, and were stabilized by diffusion to 60% MPD. Precession photographs show that the space group is P4₁ or P4₃, with cell dimensions a = b = 45.29 Å, c = 24.73 Å. The unit cell contains eight strands, with one double helix of 9 bp in the asymmetric unit. A total of 1,786 reflections were measured between 25.0 and 2.7 Å on a diffractometer. These were corrected for the Lorentz factor, polarization and absorption effects, and then symmetry-equivalent reflections were averaged. Of the 1,459 unique reflections obtained, slightly fewer than 50% in the range 3.0-2.7 Å have intensities $I > \sigma(I)$. Thus, the resolution is approximately 3.0 Å.

The unit cell dimensions suggested that our crystal structure might be nearly isomorphous with those of d(CCGG) and d(GGCCGGCC), both of which crystallize in the related space group P4₃2₁2 with 4 bp in the asymmetric unit^{13,14}. Hence, the starting coordinates for the 9-bp double helix in P43 were taken from our previously published model for poly(dG).poly(dC)¹⁵ and imposed on the coordinates of two d(CCGG) molecules in space group P4₃2₁2, with an appropriate shift in the origin. The model was refined against the X-ray data, first as a rigid body16 and then as a set of individual atoms connected by distance restraints17. Each atom in a base, sugar or phosphate group was assigned a temperature factor of 36, 41 or 46 Å², respectively, based on an overall temperature factor 18 for the crystal of 40 Å² These were not refined further due to the limited number of observations. Many electron density maps were calculated to follow the progress of the refinement. No solvent molecules were included in the phasing model because the resolution was relatively low. After 80 cycles of refinement, the agreement, or 'R-factor', between measured and calculated structure factors for all 1,032 zero-sigma data in the range 10.0-3.0 Å is 33%. The R-factor for the same phasing model, but with the X-ray data weighted according to their observed standard deviations, is 18%. Further efforts to test the correctness of our structure

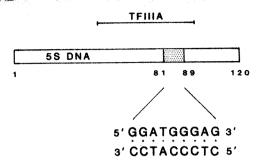

Fig. 1 A one-dimensional representation of the 120-bp codingregion for 5S RNA which shows the position of nucleotides 81-89 and the binding site for TFIIIA⁷. The numbering scheme used places the start of transcription at nucleotide 1.

solution are described in the legend to Fig. 2.

The double helix formed by d(GGATGGGAG) and its complementary strand d(CTCCCATCC) is shown in Figs 2 and 3. The identity of the bases cannot be assigned with certainty at 3 Å resolution, as the contribution of the bases to the calculated X-ray intensities does not change very much when the molecule is turned upside-down, by rotating it about its central axis of approximate 2-fold symmetry. Nevertheless, the positions of the sugar-phosphate chains, which give the overall shape of the structure, are defined clearly by the electron density and, in either orientation of the molecule, these positions refine to closely similar fractional coordinates. Figure 2 shows a view of the molecule looking into the minor groove. This groove is shallow, but not flat, and its width (as measured by the distance between phosphorus atoms) varies from 15.7 Å near the bottom of Fig. 2 to 14.3 Å near the top. By way of comparison 19, for example, fibre A-DNA has a minor-groove width of 17.0 Å, and fibre B-DNA, 11.7 Å.

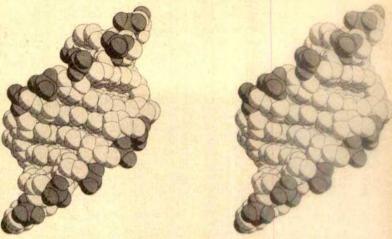

Figure 3 shows a view of the molecule looking into the major groove. This groove is both deep and wide, the mean separation of phosphorus atoms being 14.8 Å (s.d. 0.1 Å). In the model for fibre A-DNA, the major groove width is 8.2 Å, and in the model for B-DNA, 17.0 Å. Along each strand, the distances between adjacent phosphates vary considerably about a mean of 5.9 (0.6) Å. Thus, the structure seen here is clearly distinct from models of DNA which are shown in textbooks.

The ways in which the base-pairs stack on each other are described directly by the parameters 'slide' and 'roll'20. Slide is the distance by which the base pairs slip over each other in the direction of their long axes: in this structure the mean slide is 1.5 (0.7) Å. Roll, the angle by which adjacent base pairs open to the minor groove, averages 5 (13)°. The orientation of the base pairs can also be described in terms of parameters calculated relative to an imaginary helix axis. In our structure, the mean twist of base pairs with respect to this axis is 31.3 (9)°, yielding a loosely defined helical repeat of 11.5 bp. Other global parameters are the rise per residue of 3.0 (0.3) Å, a base-pair tilt of +10 (6)° and a displacement of base pairs from the central axis by 4.2 (0.3) Å. These averaged values are very close to those of the uniform model derived from the A' X-ray diffraction intensities of fibrous RNA^{21,22}. The model for A'-RNA has a helical repeat of 12.0 bp, a rise per residue of 3.0 Å, a base-pair tilt of +10° and a displacement of 4.5 Å.

Although some of the results from nuclear magnetic resonance experiments on DNA fragments in solution have been interpreted as being due to B-form structures, it is doubtful whether the technique can distinguish between the various global conformations of DNA such as 'A' and 'B'²³. However, as in the case of proteins, the three-dimensional structure of a DNA molecule in a highly hydrated crystal might indeed be the viable model for its stable conformation in vivo.

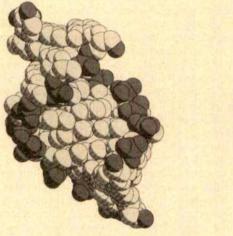

The results of our X-ray diffraction studies therefore agree with the proposal of Rhodes and Klug² that the DNA-binding

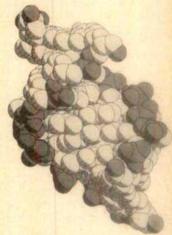

Fig. 2 Stereoscopic view the of structure of d(GGATGGGAG) and its complement d(CTCCCATCC), looking into the minor groove. Atoms P, C, N and O are represented by spheres of radii 1.9, 1.6, 1.5 and 1.4 Å, respectively; phosphate groups are shaded. In this view, the predominantly purine strand is on the left, with base G₈₁ at bottom. It is possible that the double helix packs in the crystal in a statistical fashion, using two orientations which are related to one another by a rotation of 180° about a line through the central base pair and perpendicular to the page. To assess the relative occupancies of these two possible orientations, the structure was refined independently in both settings. After 40 cycles in either case, the R-factor between measured and calculated structure factors (not weighted for noise) for all zero-sigma data to 3 Å was 33% for the model shown here, and 36% for the other orientation. Thus, it is not possible at present to determine which of the two orientations is preferred, but the

one shown here agrees marginally better with the data. In both orientations, the cytosine base nearest to the crystallographic 4-fold screw axis (C₈₉ or C₈₁) is poorly defined in the electron density. As a check, we also analysed the structure using a real-space search program²⁸, choosing as models the coordinates of fibre B-DNA, fibre A-DNA¹⁹ and, as a control, those of the refined crystal structure. Searches were carried out in both P4₁ and P4₃. At low resolution, in the range 25-10 Å, the best solution for the B-model yields an R-factor of 40%, while both the A-model and the crystal coordinates yield a much lower 30%. At moderate resolution, in the range 10-5 Å, the best solution for the A-DNA fibre model yields 50% in both P4₁ and P4₃, whereas the refined crystal coordinates yield 22% in P4₃, but 52% in P4₁. These results confirmed the choice of space group as P4₃, and further showed that the crystal X-ray structure is distinct from either the A or B forms of DNA found in pulled fibres^{19,29-32}.

Fig. 3 Stereoscopic view of the structure showing the major groove (centre) and parts of the minor groove (top left and bottom right); the purine strand is on the right, with base G₈₁ at bottom. Based on methylation protection and nuclease digestion data, Fairall et al.9 have proposed a model for TFIIIA binding to 5S DNA in which the protein lies on one side of the double helix with its 'fingers' inserted every half-turn into the major groove. The fingers of the protein are hypothesized to fold as a twisted β -sheet³. Clearly, there is plenty of room for a twisted β -sheet to fit into the major groove shown in this figure. The ability of proteins to fit into the major groove of A-form double helices has been emphasized recently by Arnott³³. A further consequence of their model is that the protein residues between adjacent fingers would span the minor groove of the DNA, a distance which in our crystal structure is 15 Å. There is an invariant tyrosine or phenylalanine in these regions of the protein; this residue could lie in van der Waals contact with the exposed sugar rings of the minor groove,

just as the terminal base pairs of DNA helices stack on the sugar residues of symmetry-related DNA molecules in this and many other structures 13-15,26. Huber and Wool 34 have studied the complex of TFIIIA with 5S RNA in solution. From their observation that the protein covers approximately the same region of bases in the RNA as in the DNA, they have also proposed that the DNA could have an RNA-like structure, at least when it is bound to the protein.

site of TFIIIA has an RNA-like structure, at least for nucleotides 81-89 in the crystal. What can be said about the conformation of this DNA in solution? Rhodes and Klug2 have used Fourier methods on nuclease digestion data to show that the entire TFIIIA-binding site has an underlying structural repeat of 5.7 bp, or 11.4 bp in two repeats. Our 9-bp molecule is not long enough to show the characteristic variation in structure which accompanies this repeat. However, the local pattern of nuclease digestion for nucleotides 81-89 in solution2 may be of interest. The enzyme DNase I does not cut well on either strand between nucleotides 82 and 83 (GpA = TpC), 84 and 85 (TpG = CpA), or 86 and 87 (GpG=CpC). These steps, in our best-refined model, are those which have extremes of local conformation such that they would be resistant to DNase I cleavage24. The GpA step has a large positive roll of 27°, compared with a mean for the structure of 5°; the TpG step a very low twist of 16°, compared with a mean of 31°; and the GpG step has a high roll 17° and a high slide of 2.6 Å, compared with a mean of 1.5 Å.

Accompanying the periodicity in structure of the TFIIIAbinding site is a periodicity in sequence²: short runs of guanine bases occur once every 5.6 bp. It seems likely that the preferred geometry of base stacking at the GpG step is the origin of an RNA-like structure for this region of DNA. Steps of the type GpG/CpC have now been observed in eight single-crystal X-ray structures: d(\(^1\)CCGG()\(^1\)3, d(GGCCGGCC)\(^1\)4, d(GGGCCCCC)\(^2\)5, d(GGGCCCCC)\(^2\)5, d(GGGATCCC) (U. Heinemann, unpublished results), d(GGTATACC)\(^2\)6 and d(GGATGGGAG). In all of these, the five-membered ring of one guanine base lies above the six-membered ring of its neighbour. Such a local base-to-base overlap is characteristic of all A-form double helices: the sideways slippage of base pairs generates a double helix with a large hole in the centre when viewed from above\(^{15,20}\).

Many other important DNA control regions are known to contain repeats of GpG². One example is the DNA-binding site for transcription factor Sp1, which contains repeats of the sequence GGGCGG²⁷. The structure of such control regions should resemble that shown here and in the other crystals mentioned.

We thank Dr A. Klug for suggesting the project, Drs B. Luisi

and M. F. Perutz for help with data collection, and especially Drs H. R. Drew and D. Rhodes for encouragement and advice. The work was supported by an MRC Program Grant (to O.K.).

MATTERS ARISING

The mechanism of activation of porcine pepsinogen

IN a recent paper we studied the early events in the activation of porcine pepsinogen using fluorescence-detected stopped flow kinetics1. We characterized two first-order decays when working with both native pepsinogen and a covalent conjugate between the fluorescent moiety 6-(ptoluidinyl)-naphthalene-2-sulphonyl- and pepsinogen1. This result was demonstrated to be consistent with a model in which concurrent first-order transformations are undergone by two species of zymogen which are related by an ionization-dependent equilibration between them. (A sequential model was ruled out by an analysis of the data.) We hypothesized that the two species initiate two concurrent pathways of activation. Subsequently, James and Sielecki, in an extrapolation from their new crystallographic structure of porcine pepsinogen, also proposed two alternative pathways for activation². They did not explicitly suggest, however, that the two paths are followed simultaneously under a given set of conditions. It will be noted that their proposal bears a close resemblance to the model we had already worked out' based on the kinetic analysis described above. Most recently we have demonstrated that the pH-dependent segregation of pepsinogen molecules between alternative pathways persists at least through the process which exposes the active site³. This was shown by following the kinetics of binding of a fluorescent analogue of pepstatin to pepsinogen upon acidification. It was again observed that there are two firstorder processes consistent with the concurrent reaction model described above.

The crystal structure of pepsinogen reported by James and Sielecki² permits a much clearer understanding of the origins of the changes in intrinsic fluorescence that we obtained1. They noted that the environment of at least four tyrosyl residues must be perturbed upon release of Lys 36P (residues 1P-44P comprise the activation peptide) from its electrostatic interaction with the carboxylates of the catalytically-active residues Asp 32 and Asp 215. The fluorescence changes that we observed occur on the millisecond time scale, and are followed by no further change for several seconds¹. This strongly suggests that very soon after acidification the activation peptide is released from its initial position in which it blocks the catalytic site².

The distinguishing conformational features of the two molecular species of acidified pepsinogen, which form a Bronsted acid-base conjugate pair, remain to be identified. Further studies by us, as well as results obtained by crystallographic analysis, may provide a means to this end.

JAMES AND SIELECKI REPLY-Acid activation of porcine pepsinogen has long been known to involve conformational changes^{1,2} that can be reversed by rapidly returning the pH of the solution to neutrality. Conformational changes on a time scale of 5 ms-2 s have also been detected by stopped flow fluorescence kinetics.3 Analysis of these data suggests that there are two concurrent activation pathways for pepsinogen. Exposure of the active site of the enzyme occurs on roughly the same time scale (1-2 s). The kinetic

data for the binding of a fluorescent pepstatin analogue are also interpretable in a two concurrent pathway model.4

The crystal structure of porcine pepsinogen has shown that the pepsin active site is fully formed in the zymogen but that it is blocked competitively by the specific folding of the activation peptide (Leu1P-Leu44P). This blocking takes place in a manner different from that expected for productive substrate binding. The two alternative steps in the proposed activation pathway⁵ are concerned only with repositioning the activation peptide so that the scissile bond (Leu16P-Ile17P) can approach the catalytic aspartates. This cleavage step has a relatively longer halftime of ~28 s (ref. 6). Unfortunately, a static crystal structure cannot provide definitive data on dynamic events that are occurring at millisecond or second time scales. However, the three-dimensional structure allows us to propose the two alternative pathways for productive binding of the scissile peptide bond of pepsinogen in the unimolecular cleavage reaction. Whether our alternative binding modes are associated with relatively rapid fluorescence changes and the concurrent pathways so deduced remains to be seen.

We thank Drs Auer and Glick for the opportunity to read their manuscript⁴ prior to publication.

The laboratory networking dilemma

from W.H. Jennings

Computer networking in the research laboratory is still a rarity. But growing demands for shared resources may prompt laboratories to make the connection . . . the question is when and how.

WITH the advent of microcomputers, data acquisition and control became dominated by systems dedicated to or embedded within the research instrument. The constraints of real-time operation and the limited computational capacity of these systems favours the transfer of raw data files to another machine for computationally intensive processing. While most scientists are familiar with this sort of transfer, local area networks that make the various computers within a department accessible to all department staff are still uncommon. Yet many research laboratories could benefit enormously from systems that distribute data to the computer most appropriate for a particular computational task.

Presently, moving data between machines is often accomplished by media transfer using magnetic tape or some form of disk, the difficulties of media transfer have encouraged the development of file transfer techniques that use serial transmission to transport data, often via telephone lines. Although vendors have been dragging their feet in devising common file format and transfer protocols for larger machines, several reasonably documented protocols exist for personal computers, and some of these have been adapted to large machines. There is then the potential for any computer-based laboratory instrument to transfer data to a departmental host machine or even some remote computer.

But realizing this potential at a level truly useful to laboratory scientists requires networking technology, and this technology is in flux. Herein lies the first element of the dilemma: when is it appropriate for a laboratory to implement a computer network?

Choosing the moment

Unfortunately, very few laboratories have the luxury of implementing a network de novo because of the computer-based instruments and/or the relatively expensive departmental computers they may have already accumulated. Interconnecting a variety of vendors' products, some of which may be obsolete, can pose problems. And of the many network products now available, there is probably no one product that is appropriate for all laboratory applications.

Nonetheless, rather straightforward means are available to remedy most of these complications, even though in some cases the solutions may be only marginally adequate. Networks are intrinsically expandable and extensible and their future value may be far more important than present economic or productivity gains. Current network standards offer both physical connectivity with fairly long lifetimes and protocols that, being software,

cannot be upgraded with a network interface can gain network access through terminal concentrators, which accept RS-232 serial transmissions and perform the necessary hardware and software functions to interface to the network. This access is limited in functionality and

Computer networks at work

A network comprised of 5 km of cable is tied to seven systems in separate facilities

Over 300 IBM and DEC microcomputers are linked by a minicomputer intermediary

can be upgraded. There is then no compelling argument here to wait for further developments.

In fact, the decision to implement a laboratory network does not depend so much on issues of technology as on the commitment of laboratory personnel and funding. Even though its tangible portions may be limited to cables and connectors, a network requires considerable management and support, and in most labs these functions must be provided by existing personnel. Because the majority of networks are implemented at the departmental level rather than in top administrative or corporate echelons, the laboratories that will share the network usually have to dip into their own financial and personnel resources to sustain it.

The department that has decided to commit itself to networking confronts the second element of the dilemma: how can a laboratory network its computer resources? A variety of consultants and manufacturers provide technology support for networking projects, but the development of in-house expertise is desirable for both implementation and subsequent operations management.

Casting the net

The volume and characteristics of the data handled within a laboratory will determine a rough lower limit for network capacity. Generous margins should be added to allow expansion. Where very high data volume is required, a limited local network with a gateway to other networks can be a worthwhile option.

"Dumb" terminals and instruments that

speed: however, it is adequate for the majority of these devices.

The nearly ubiquitous personal computer can be connected either directly through an interface card or indirectly through a terminal concentrator. Terminal emulation software disguises the personal computer so that it appears to a remote computer as one of a variety of popular terminals. The networked PC can thus perform interactive file manipulation and execute programs on the remote system. Most emulation software provides for file transfer to or from the remote as well

Techniques for access and sharing of files and programs throughout a network are being extensively tested on advanced networks of more than 1,000 nodes. Meanwhile the next generation of computer systems, the personal workstation, is beginning to appear in the research laboratory. This device has a large memory, high resolution graphics and computational power exceeding that of some minicomputers. Most are sold with a network interface and AT&T's operating system UNIX, which already contains many networking functions.

The goal of networking is to make efficient use of computer resources, providing access to any level of computational power that the user might require without the bother of juggling cables, connections or conversions. For any laboratory ready to commit modest resources, this goal is already in sight.

William Jennings is at the National Institutes of Health, Room 108, Building 2, Bethesda, Maryland 20892, USA.

The binary breakthrough

From data acquisition to manuscript submission, computers aid research every step of the way and the computers often jump in where their owners may fear to tread.

WITTIN weeks, California-based Intelli-Genetics will be releasing molecular biology software that the company says can perform over 50 analyses of peptide and nucleic acid structure, both primary and secondary (Reader Service No. 100). The

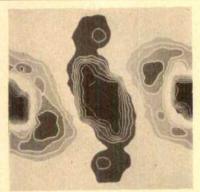

PC/GENE is based on published methods.

PC/GENE microcomputer package will search for specified sequences, predict helix distortion and hairpins, find probable coding regions and simulate restriction digestions. Capable of drawing over 20 different types of plots, PC/GENE runs on IBM PCs and compatibles with graphic cards. IntelliGenetics' commercial price is \$3.500 (US); academic institutions can purchase the package for \$2.500 (US) and BIONET subscribers gain access to PC/GENE at no additional cost. Programs allow file transmission between PC/GENE and BIONET, the company's mainframe timesharing system.

Two software packages for protein analysis and restriction mapping are among DNASTAR's offerings for molecular biologists (Reader Service No. 101). The company says its protein programs calculate plots of secondary structure and hydrophilicity by two different methods, and can determine optimal DNA probes, titration curves, isoelectric points and molecular weights. DNA-STAR asks about \$3,000 (US) for that package. The \$990 (US) R-MAP program derives circular or linear restriction maps from enzyme digestion data by way of an algorithm that the company claims is unique. Both products run on IBM PCs and compatibles.

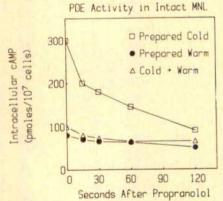

Chemical Design Ltd thinks its latest addition to the Chem-X molecular modelling family will make traditional laboratory notebooks obsolete (Reader Service No. 102). Chem DBS-1 is a database software module that also automatically records the results of Chem-X calculations and accompanying comments. Energy

A Chem-X energy analysis map for histamine. values, significantly positive or negative map volumes and user-defined geometries can be stored in DBS-1, in addition to structural information on several hundred molecules. "Pages" containing records of Chem-X calculations such as molecular fitting and spatial analyses can be located later by page number, date of entry, type of calculation and molecular name. Chemical Design's turnkey system Micro-GRAF-4, which starts at \$95,000 (US). incorporates Chem-X software for DEC MicroVAX II. DBS-1 will be demonstrated at September's ACS meeting in Anaheim.

Graphic detail

Plotting presentable graphs is the aim of software from Academic Press called Graph-PAD (Reader Service No. 103). Using an IBM PC with graphics capabilities and a Hewlett-Packard plotter or compatible equipment, the program can

Academic Press's program can graph multiple

plot bars, data points or curves from any of 10 available equations. Graph-PAD accepts data typed into a spreadsheet or contained in external files. The program can also digitize existing graphs via a plotter pen. Data manipulation features include calculations of average replicate values.

error bars, linear regressions and logarithmic transformations. Academic Press says no computer experience is necessary to be able to create graphs in less than 10 minutes and offers a \$5 (US) demonstration disk to make its point. The com lete diskette and its 98-page manual cost \$340 (US).

Janssen's life sciences division now offers a novel interpretation of numerical tabular data in the form of SpectraMap (Reader Service No. 104). Unlike bar. line or pie chart graphs, Janssen's program elucidates the ratios generated from problems involving many parameters. SpectraMap uses factor analysis and advanced computer graphics to arrive at a display complex enough to require instructions for interpretation. The company says its profiles can be applicable to studies in disciplines ranging from biophysics to epidemiology. Janssen provides the service on a piecemeal basis starting at £150 (UK) per graph. Alternatively. licensing of SpectraMap's PC version for £2,535 (UK) can be arranged for regular

Mathematical equations are unruly entities in the word-processing world. But recently a Massachusetts company, Technical Support Software, began marketing

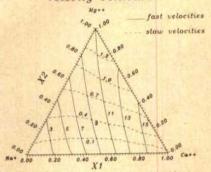

EXACT puts mathematics in the picture.

typesetting software that enables scientific and mathematical expressions to be incorporated into standard word-processing text and printed on garden-variety printers (Reader Service No. 105). Called EXACT, the program loads into RAM before the word processor and performs split-screen editing within the context of the target document. The editing mode displays characters exactly as they will appear in the printed document, automatically re-scaling radicals, braces, brackets, parentheses and boxes. EXACT's vocabulary includes 20 different fonts and over 1,000 symbols and characters. TSS guarantees its program on any word processor and sells a demo disk at \$5 (US); the real thing cost \$475 (US).

The chore of visualizing relationships amongst large data volumes is simplified with GRAPHER. Golden Software Inc's answer to plotting (Reader Service No. 106). With five types of regression curves, four types of error bars and graphs includ-

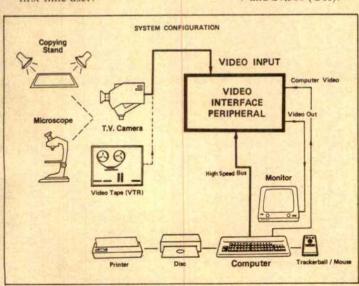

ing linear-linear, linear-log and triangular, GRAPHER can unveil the implications obscured by sheer numbers. It will Velocity Contours

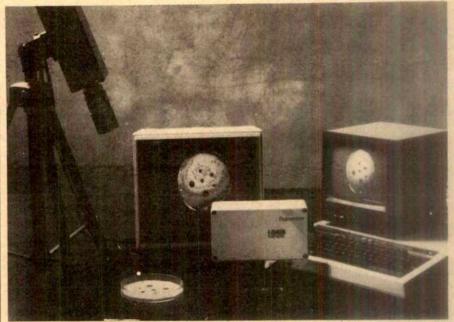

Complex relationships come to light with GRAPHER.

generate grid lines and any number of data scales or data lines can be combined on one graph. The \$199 (US) program's worksheet loads from keyboard or external data files; it will annotate graphs with text. Golden says GRAPHER runs on IBM PCs and compatibles with several kinds of graphics adaptors. A \$10 (US) demonstration disk can be supplied upon request.

A personal software series for chemists comes from ECS Chemical Systems in the UK (Reader Service No. 107). From CHEMTALK, a £1,000 (UK) program, to CHEMBASE, the series' modelling component. ECS's software aids in the storage, retrieval and display of chemical information. A hand-held mouse can select commands, draw structures or assemble reactions. The graphics-based word processor CHEMTEXT accepts transfers from CHEMBASE, while CHEMHOST and CHEMTALK link mainframe databases to the PC software. ECS expects its system to accelerate research formerly harnessed with the tedium of producing polished reports by hand. The IBM-compatible software boasts 500 different help screens for the first-time user.

Slight Systems has designed its image analyser to accept many different video sources and give standard video output. The Video Interface Peripheral can also be used as a video event recorder. The system employs a high order of noise reduction, and a phase lock circuit synchronizes the VIP to the incoming video.

In this FrameStore configuration, the right monitor shows a monochrome digitized image and the left displays the image with false colour generated by Data Harvest software.

Worth 1,000 words?

A menu-driven image analysis system from Sight Systems uses two video frame stores with 512×512 resolution for image storage (Reader Service No. 108). The grey and binary framestores of the company's Video Interface Peripheral (VIP) work in tandem at video rate; the menu that occupies one quarter of the screen provides a space for text and headings for routines or measuring processes. Sight Systems' analyser also achieves fast thresholding, according to the company. providing an image that is simpler to understand than unembellished images. The computer can read or write to any pixel in the binary store, grey store or menu area at any time. Because the VIP can analyse images live with no adverse affects, pseudo-real time analysis is possible, says Sight Systems. The company sells VIP in configurations costing between £2,000 and £4,500 (UK).

Data Harvest has pulled the price of its FrameStore analyser down to £395 (UK) (Reader Service No. 109). The company says its economy-line system can distinguish up to 64 discrete levels of image intensity and provide resolution of 192 × 256 pixels. A microcomputer allows manipulation, processing or transfer of digitized data. Because outlines can be identified through contrast enhancement. FrameStore can make area measurements/ratios calculations by pixel count. The analyser accepts video signals from sources such as video cameras, cassette recorders and disks and can be purchased separately or as part of a complete video

A desktop X-ray microanalysis system has been introduced as an "economic

Link Systems backs up the QX200 with full support services.

alternative" by Link Systems in High Wycombe (Reader Service No. 110). The company says its model QX200 offers display capabilities ranging from on-screen peak seek to labelling and KLM identification, and stores data via 3.5-inch floppy drives. Extensive data acquisition and manipulation capabilities are part of the OX200 package, as well as spectrum processing. A mouse is optional to simplify operating procedures, and the £24,000 (UK) system includes a bidirectional printer/plotter. Link says that in addition to the quantitative X-ray microanalysis program included with the package, an extended range of application software is available.

Designs for data

Computer analysis without computer expertise is the promise of Macmillan software's ASYSTANT package (Reader Service No. 111). The new software, says Macmillan, puts advanced application functions in a menu-driven format for ease of use. The company's basic \$495 (US) package performs integrated data reduction and analysis with high-resolution colour graphics; an \$895 (US) version

ADVERTISEMENTS

Reader Service No.12

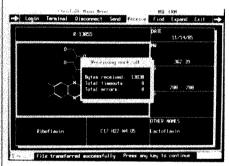

Reader Service No.50

called ASYSTANT+ adds data acquisition capabilities to the basic software. Macmillan's programs are designed for IBM personal computers.

A PC program from Laboratory Technologies Corp builds a bridge between the company's LABTECH NOTEBOOK data acquisition software and standard PC/MS-DOS applications programs (Reader Service No. 112). LABTECH Real Time Access, a \$195 (US) option for the \$895 (US) acquisition package, moves data samples from NOTEBOOK directly into spreadsheet, statistical data analysis, data base management and display programs. Hence the numbers generated by an external process and acquired by NOTEBOOK could appear in real time. continuously updated, on a Lotus 1-2-3 worksheet.

Nearly a decade of experience in chemical database management has given rise to MACCS-II, an integrated and customizable information system from Molecular Design (Reader Service No. 113). The company claims that the advantage of its latest system lies in its potential to be

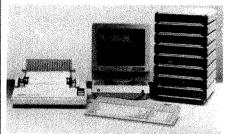

MACCS-Hallows custom design of help menus.

tailored to particular circumstances in particular laboratories. With a flexible program sequence language, MACCS-II simplifies operations and automation. Information such as test results, statistical analyses and graphic output from laboratory instruments can all be accessed via MACCS-II, and pooled in hard copy reports.

Life for LIMS

Tips on improving the performance and security of laboratory information management systems (LIMS) abound in a technical bulletin from Beckman (Reader Service No. 114). The bulletin uses Beckman's recent revision of its own CALS LabManager product to illustrate measures that can simplify organization and protect data copies. By dividing active samples from completed samples within the database. Beckman reports, the company was able to improve search time for many retrievals and create back-up versions of the completed base. Such insurance against disk drive failures provides the rationale for Beckman's Lab-Manager Safegard as well, an optional configuration that automatically maintains mirror images of active sample files on a separate disk.

In designing its LIMS, Trivector Systems tried to develop a network microcomputer approach rather than build the

A turnkey service is available for TRINET system around a centralized super-minicomputer (Reader Service No. 115). The result: TRINET, an information manager that Trivector hopes will provide both modest beginnings and considerable potential for expansion. At the heart of the system, a dedicated information manager with ports for up to 16 stations coordinates data management, whilst the stations are engaged in manual input, enquiries, program development and data transfer or collection. A database management package with its own screen and report generation programs makes LIMS design quick and easy, according to Trivector, which asks £15,000 (UK) and up for TRINET.

Guides to programs

A brochure detailing Fisher's toxic substance database shows full-colour examples of the program's display (Reader Service No. 116). These glimpses of ChemPro give a fair idea of the software's functioning, which gives information on any of 4,100 hazardous chemicals most frequently found in research laboratories, according to the company. Fisher kept the program's format uncomplicated so that substances could be located quickly in an emergency, and there are special keys for fires, spills and poisonings. ChemPro runs on an IBM AT.

The scientific software and educational programmes marketed by Autoscribe Ltd are reviewed in the company's latest catalogue (Reader Service No. 117). Autoscribe offers software such as Molecular Presentation Graphics for chemical structure drawing and Datalyst for chemical databases. Educational programmes are available on various media. The company hopes to expand both its education and software ranges shortly.

These notes are compiled by Karen Wright from information provided by the manufacturers. To obtain further details about these products, use the reader service card bound inside the journal. Prices quoted are sometimes nominal and apply only within the country indicated.

Astrophysics of Active Galaxies and Quasi-Stellar Objects. By J.S. MILLER. Oxford University Press:1985. Pp.519. Hbk ISBN 0-19-8557-17-5. £37.50.

Beyond the Black Hole: Stephen Hawking's Universe. By JOHN BOSLOUGH. Fontanal Collins: 1986. Pp. 127. Pbk ISBN 0-00-636652-X. £2.50.

Birth and Evolution of Massive Stars and Stellar Groups. W. BOLAND and H. VAN WOERDEN (eds). D. Reidel: 1985. Pp. 377. Hbk ISBN 90-277-2135-1. Dfl. 150, £41.75, \$59.

Early History of Cosmic Ray Studies: Personal Reminiscences with Old Photographs. YATARO SEKIDO and HARRY ELLIOT (eds). D. Reidel: 1985. Pp. 444. Hbk ISBN 90-277-2083-5. Dfl. 250, £69-25, \$89.

Mass Loss from Red Giants. MARK MORRIS and BEN ZUCKERMAN (eds). Reidel:1985. Pp.320. ISBN 90-277-2075-4. Dfl.135, \$49.

The Planet Sun (enlarged 1985 edition). By TASSOS A. KAROUSATOS. Laboratory of Magneto-Optical Research, 43 Levidou Street, GR-145 63. Kifissia, Athens, Greece:1985. Pbk np.

Supernovae. By PAUL and LESLEY MURDIN. Cambridge University Press:1985. Pp.185. Hbk ISBN 0-521-30038-X. £12.95, \$24.95.

Physics

Advanced Fracture Mechanics. By MELVIN F. KANNINEN and CARL H. POPELAR. Oxford University Press: 1985. Pp. 563. ISBN 0-19-503532-1. £40.

Amorphous Solids and the Liquid State, NORMAN H. MARCH, ROBERT A. STREET and MARIO TOSI (eds). Plenum:1985. Pp.339. Hbk ISBN 0-306-110475-8.

Cryogenic Systems, 2nd Edn. By RANDALL F. BARRON. Oxford University Press: 1985. Pp. 507. ISBN 0-19-503567-4. f60.

Desorption Induced by Electronic Transitions. W. BRENIG and D. MANZEL (eds). Springer-Verlag: 1985. Pp.291. ISBN 3-540-15593-7/0-387-15593-7.

Dynamical Phenomena at Surfaces, Interfaces and Superlattices. F. NIZZOLI, K.H. RIEDER and R.F. WILLIS (eds). Springer-Verlag:1985. Pp.329. ISBN 3-540-15505-8/0-387-15505-8. DM 89.

Elements of Modern Optical Design. By DONALD C. O'SHEA. Wiley: 1985. Pp. 402. Hbk ISBN 0-471-07796-8. £40.85.

Foundations of Quantum Mechanics II. By G. LUDWIG. Springer-Verlag: 1985. Pp. 416. Hbk ISBN 3-540-13009-8. DM 228.

Fundamental Interactions in Low-Energy Systems. P. DALPIAZ, G. FIORENTINI and G. TORELLI (eds). Plenum:1985. Pp.501. ISBN 0-306-42002-3.

Fourier Techniques and Applications, JOHN F. PRICE (ed.). Plenum:1985. Pp.231. Hbk ISBN 0-306-42100-3. Np.

Introduction to Concepts and Theories in Physical Science (2nd Edn.). By GERALD HOLTON, revised and with new material by STEPHEN G. BRUSH. Princeton University Press:1985. Pbk ISBN 0-691-08284.2 \$10.05

Molecular Electromagnetism. By A. HINCHLIFFE and R.W. MUNN. Wiley:1985. Pp.252. Pbk ISBN 0-471-90721-9. Pbk £9.95.

Applied Biological Sciences

Advances in Cancer Research, Vol.45. Academic: 1985. Pp.324. Hbk ISBN 0-12-006645-9. £48, \$55.

Advances in Human Genetics, Vol.15. H. HARRIS and K. HIRSCHHORN (eds). *Plenum:1986. Pp.299. Hbk ISBN 0-306-42155-0. Np.*

Advances in Veterinary Science and Comparative Medicine, Vol.30. CHARLES E. CORNELIUS and CHARLES F. SIMPSON (eds). Academic:1985. Pp.339. Hbk ISBN 0-12-039299-1. £52, \$59.50.

Advances in Pain Research and Therapy. Vol.9, Proceedings of the Fourth World Congress on Pain. HOWARD L. FIELDS, RONALD DUBNER and FERNANDO CERVERO (eds). Raven Press:1985. Pp.951. Hbk ISBN 0-88167-121-5. \$153.

Animal Behaviour and Its Applications. By DEREK V. ELLIS. Lewis Publishers: 1985. Pp. 329. Hbk ISBN 0.87371-020.7-627-55

Aortitis: Clinical, Pathological and Radiographic Aspects, ADAM LANDE, YAHYA M. BERKMEN and HUGH A. McALLISTER, Jr (eds). Raven 1085 Pp. 288 Hist. IERN 0.88167, Ltd. V. S. 3.50.

1985. Pp. 288. Hbk ISBN 0-88167-141-X. 563.50. Atlas of Cancer in Scotland 1975-1980: Incidence and Epidemiological Perspective. I. KEMP, P. BOYLE, M. SMANS and C. MUIR (eds). IARC Scientific Publications, Lyons:1985. Pp. 282. Hbk ISBN 928-321172-3. £35.

The Autoimmune Disease, NOEL R. ROSE and IAN R. MACKAY (eds). Academic:1986. Pp.727. Hbk ISBN 0-12-596920-1. £75, \$85.

Bacteria and Complement. Current Topics in Microbiology and Immunology, Vol.121. MICHAEL LOOS (ed.). Springer-Verlag:1985. Pp.191. Hbk ISBN 3-540-15877-4. Np.

Biological Effects and Dosimetry of Static and ELF Electromagnetic Fields. M. GRANDOLFO, S.M. MICHAELSON and A. RINDI (eds). *Plenum:1985*. *Pp.697. Hbk ISBN 0-306-41923-8. Np.*

Biology of Sewage Treatment and Water Pollution Control. By K. MUDRACK and S. KUNST. Ellis Horwood: 1986. Pp. 193. Hbk ISBN 0-85312-912-6. £27.50.

Biorhythms and Epilepsy. A. MARTINS DA SILVA, C.D. BINNIE and H. MEINARDI (eds). Raven:1985. Pp.254. Hbk ISBN. 0-88167-124-X.

Capnography in the Operating Room, an Introductory Directory. By W. SAMUEL MAY Jr. JAMES E. HEAVNER, DOROTHY McWHORTER and GABOR RACZ. Raven Press:1985. Pp.64. Pbk ISBN 0-88167-128-2. \$14.00.

Cell Culture and Somatic Cell Genetics of Plants. Vol.2, Cell Growth, Nutrition, Cytodifferentiation and Cryopreservation. INDRA K. VASIL (ed.). Academic:1985. Pp.330. Hbk ISBN 0-12-715002-1. £42 50 849 50

Cell Membranes and Cancer, T. GALEOTTI, A. CITTADINI, G. NERI, S. PAPA and L.A. SMETS (eds). Elsevier:1985. Pp. 446. Hbk ISBN 0-444-80723-3. Dfl. 230, \$85, 25.

Chemotherapy of Parasitic Diseases. WILLIAM C. CAMPBELL and ROBERT S. SHAW (eds). Plenum:1986. Pp.655. Hbk ISBN 0-306-42029-5. Np.

Congenital Adrenal Hyperplasia. MARIA I. NEW (ed.). New York Academy of Sciences:1985. Pp.290. ISBN 0-89766-311-X. Np.

Contact Allergy Predictive Tests in Guinea Pigs. Current Problems in Dermatology, Vol.14. K.E. ANDERSEN and H.I. MAIBACH (eds). Karger: 1985. Pp.300. Hbk ISBN 3-8055-4053-1. SFr. 162, DM 194, £50.70, \$69.00.

Contemporary Issues in Pesticide Toxicology and Pharmacology. By JUDITH K. MARQUIS. Karger: 1986. Pp.108. Hbk ISBN 3-8055-4215-1. SFr. 89, DM 107-677-90, \$38

Control of Animal Cell Proliferation, Vol.1. ALTON L. BOYNTON and HYAM L. LEFFERT (eds). Academic:1985. Pp.557. Hbk ISBN 0-12-123061-9.£60.50, \$68.50.

Control of Pig Reproduction II. Proceedings of the Second International Conference on Pig Production Held at Columbia Missouri, USA. G.R. FOXCROFT. D.J.A. COLE and BARBARA J. WEIR (eds). Journal of Reproduction and Fertility: 1985. Pp. 266. Hbk ISBN 0-906545-10-2, \$63.

Deep Dyslexia. MAX COLTHEART et al. (eds). Routhledge & Kegan Paul: 1986. Pp. 444. Pbk ISBN 0-7102-0834-0. Pbk F8 95.

Dietary Fiber and Obesity. Current Topics in Nutrition and Disease, Vol.14. Alan R. Liss:1985. Pp. 126. Hbk ISBN 0-8451-1613-4. £17.

Ear, Nose and Throat Disorders in Children. By JOHN E. BORDLEY, PATRICK E. BROOK-HOUSER and GABRIEL FREDERICK TUCKER, Jr. Raven:1985. Pp.456. Hbk ISBN 0-89004-324-8. \$52.50.

Economic Aspects of Biotechnology. Cambridge Studies in Biotechnology. By ANDREW J. HACK-ING. Cambridge University Press: 1986. Pp. 306. Hbk ISBN 0-521-25893-6. \$39.50.

Epidemiology of Leukaemia and Lymphoma, M.F. GREAVES and L.C. CHAN (eds). *Pergamon: 1985. Pp.163. Hbk ISBN 0-08-032002-3. £19, \$25.*

Equine Surgery and Medicine, Vol.1. JOHN HICK-MAN (ed.). Academic:1985. Pp. 398. Hbk ISBN 0-12-347221-0. £69.50. \$80.

Evaluation of Cyclamate for Carcinogenicity. Commission on Life Sciences, National Research Council. National Academy Press, Washington, US:1985. Pp. 196. Pbk ISBN 0-309-03546-5. Pbk Fl4 50.

Forest Ecosystems: Concepts and Management, By RICHARD H. WARING and WILLIAM H. SCHLESINGER. Academic:1985. Pp. 340. Hbk ISBN 0-12-735440-9. £39.50, \$45.

Gaba and Mood Disorders: Experimental and Clinical Research. L.E.R.S Monograph Series, Vol.4. G. BARTHOLINI, K.G. LLOYD and P.L. MORSELLI. Raven Press:1986. Pp.240. Hbk ISBN 0-88167-129-0. \$32.50.

Gene Manipulations in Fungi. J. W. BENNETT and LINDA L. LASURE (eds). Academic 1986. Pp.558-Hbk ISBN 0-12-088640-5. £65, \$75.

Genetic Approaches to Microbial Pathogenicity. Current Topics in Microbiology and Immunology, Vol.118. W. GOEBEL (ed.). Springer-Verlag:1985. Pp.283. Hbk ISBN 3-540-15597-X. DM 160.

Genetic Basis of Biochemical Mechanisms of Plant Disease. JAMES V. GROTH and WILLIAM R. BUSHNELL (eds). The American Phytopathological Society Press:1985 Pp.157. Phk ISBN 0-89054-068-3. 524

Genetic Perspectives in Biology and Medicine. EDWARD D. GARBER (ed.). The University of Chicago Press: 1986. Pp. 500. Hbk 1SBN 0-226-287215-5; pbk ISBN 0-226-28216-3. Hbk £25.50; pbk £10.25.

Genetics, Cell Differentiation and Cancer. Bristol-Myers Cancer Symposia, Vol.7, PAUL A. MARKS (ed.). Academic:1985. Pp.209. Hbk ISBN 0-12-473060-4.£22.50, \$25.

Genetics and the Law III. AUBREY MILUNSKY and GEORGE J. ANNAS (eds). Ptenum: 1985. Pp.514. Hbk ISBN 0-306-41983-1. Np.

Genetics in Clinical Oncology. R.S.K. CHAGANTI and JAMES L. GERMAN (eds). Oxford University Press:1985, Pp.280. Hbk ISBN 0-19-503609-3. £35.

Hormonally Responsive Tumours. VINCENT P. HOLLANDER (ed.). Academic:1985. Pp. 558. Hbk ISBN 0-12-352560-8. £59, \$68.

Humour Therapy in Cancer, Psychosomatic Diseases, Mental Disorders, Crime, Interpersonal and Sexual Relationships. By BRANKO BOKUN. Via Books, 26 Chelsea Square, London SW3. UK:1986. Pp.221. Pbk ISBN 0-9510525-0-0. £5.00.

Hyperalimentation: A Guide for Clinicians. MITCH-ELL V. KAMINSKI Ir. (ed.) Dekker:1985. Pp.744. Hbk ISBN 0-8247-7375-6. 895 (US and Canada), \$114 (other countries).

Implantation of the Human Embryo. R.G. EDWARDS. JEAN M. PURDY and P.C. STEP-TOE (eds). Academic:1985. Pp. 459. Hbk ISBN 0-12-232455-2. £52, \$59.50.

Interrelationship Among Aging, Cancer and Differentiation. The Jerusalem Symposia on Quantum Chemistry and Biochemistry, Vol.18, BERNARD PULLMAN, PAUL O.P. TS'O and EDMUND L. SCHNEIDER (eds). D. Reidel: 1985 Pp.345. Hbk ISBN 90-277-2117-3. Dfl 145, £40.25, \$57.

Large-Scale Mammalian Cell Culture. JOSEPH FEDER and WILLIAM R. TOLBERT (eds). Academic:1985. Pp.159. Hbk. ISBN 0-12-250430-3. £22.50, \$25.

The Limbic System: Functional Organization and Clinical Disorders. BENJAMIN K. DOANE and KENNETH F. LIVINGSTON (eds). Roven Press: 1985. Pp.365. Hbk ISBN 0-88167-134-7-364-50.

Mathematical Physics. By ROBERT GEROCH. The University of Chicago Press: 1986. Pp.351. 4164. ISBN 0-226-28861-7. £25.50.

Mechanism of Menstrual Bleeding, D.T. BAIRD and E.A. MICHIE (eds). Raven:1985. Pp.276. Hbk. ISBN 0-88167-094-4, \$43.50.

Medicinal Chemistry Research in India. By HAR-KISHAN SINGH, A.S. CHAWLA and V.K. KAPOOR. National Information Centre for Drugs and Pharmaceuticals, Lucknow, India:1985. Pp.184. ISBN 81-85042-00-4. §35.

Medicinal Plants in Tropical West Africa. By B.E.P. OLIVER-BEVER. Cambridge University Press: 1986. Pp.375. Hbk ISBN 0-521-26815-X. £40, \$75.

Methods for Nutritional Assessment of Fats. JOYCE BEARE-ROGERS (ed.). American Oil Chemists Society: 1985. Pp.255. Hbk ISBN 0-935315-11-X. \$50.

Methods in Porphyrin Photosensitization. Advances in Experimental Medicine and Biology, Vol. 193. DAVID KESSEL (ed). Plenum:1985. Pp.352. Hbk ISBN 0-306-42210-7. Np.

Migraine: Clinical and Research Advances. Fifth International Migraine Symposium, London 1984. F. CLIFFORD ROSE (ed.). Karger: 1985. Pp. 280. Hbk 15BN 3-8055-4039-6. SFr. 175, DM 210, £54.70, \$74.50.

Migraine (new edn.). By OLIVER SACKS. Duckworth: 1986. Pp.270. Hbk ISBN 0-7156-2087-8.

Models for Biomedical Research: A New Perspective. Commission on Life Sciences, National Research Council. National Academy Press:1985. Pp.180. Pbk ISBN 0-309-03538-4. £19.60

Molecular Biology and Biotechnology. J.M. WALKER and E.B. GINGOLD (eds). Royal Society of Chemistry: 1986. Pp.340. Pbk ISBN 0-85186-985-8. Pbk ISSN 0-85186-985-8.

Molecular Dynamics and Protein Structure, JAN HERMANS (ed.). University of North Carolina Printing Dept.: 1985. Pp. 195. Pbk. \$10.

Monoclonal Antibodies Against Bacteria, Vol.II. ALBERTO J.L. MACARIO and EVERLY CON-WAY de MACARIO (eds). Academic:1986. Pp.,335. Hbk ISBN 0-12-463002-2. £42. \$49.

New Directions for Biosciences Research in Agriculture: High Reward Opportunities. National Academy Press:1985. Pp.122. Pbk ISBN 0-309-03542-2. £10.55.

Non-Hodgkin's Lymphomas: New Techniques and Treatments. Fourth Cancer Research Workshop, Grenoble 1984. J.J. SOTTO, C. VROUSOS, M.F. SOTTO and F. VINCENT (eds). Karger:1985. Pp.232. Hbk ISBN 3-8055-4064-7. SFr 162, DM 194, £50.70, \$69.

Nutrition in Cancer and Trauma Sepsis. F. BOZZETTI and R. DIONIGI (eds). Karger:1985. Pp.203. Pbk ISBN 3-8055-3959-2. Pbk DM 88, 831-50.

Papillomaviruses, Molecular and Clinical Aspects. PETER M. HOWLEY and THOMAS R. BROKER (eds). Alan R. Liss:1986. Pp. 598. Hbk ISBN 0-8451-2651-2631-8. F72

Parmacokinetics of Cardiovascular, Central Nervous System and Antimicrobial Drugs. Royal Society of Chemistry, London:1985. Pp.462. Hbk ISBN 0-85186-937-8, \$71, £39.

The Pathologist and the Environment. DANTE G. SCARPELLI, JOHN E. CRAIGHEAD and NATHAN KAUFMAN (eds). William & Wilkins: 1985. Pp.239. ISBN 0-683-07516-0. £47.50.

Pathology of Unusual Malignant Cutaneous Tumours. MARK R. WICK (ed.). Dekker:1985. Pp. 440. Hbk ISBN 0-8247-7377-2. (USA & Canada) \$69.75, (other countries) \$83.50.

Pedigree Analysis and Human Genetics. By ELIZA-BETH A. THOMPSON. The John Hopkins University Press:1986. Pp.213. Hbk ISBN 0-8018-2790-6. £28.50.

The Peptides: Analysis, Synthesis, Biology. Vol.7, Conformation in Biology and Drug Design. VICTOR J. HRUBY (ed.). Academic: 1985. Pp. 495. Hbk ISBN 0-12-304207-0. £85.50 \$99.

Pocket Atlas of Cranial Magnetic Resonance Imaging. By VICTOR M. HAUGHTON and DAVID L. DANIELS. Raven:1986. Pp.61. Pbk ISBN 0-88167-171-1. Pbk \$14.

Population Genetics in Forestry: Proceedings, Göttingham 1984. Lecture Notes in Biomathematics, 60. H.R. GREGORIUS (ed.) Springer-Verlag:1985. Pp. 287. Pbk ISBN 3-540-15980-0. DM 43.

Positron Emission Tomography and Autoradiography: Principles and Applications for the Brain and Heart. MICHAEL E. PHELPS et al. (eds). Raven: 1985. Pp. 690. ISBN 0-88167-118-5. \$98.50

Progress in Clinical Biochemistry and Medicine. Vol.2, Oncogenes and Human Cancer, Blood Groups in Cancer, Copper and Inflammation, Human Insulin. (Contributions by) T.L.J. BOEHM, U. DEUSCHLE, W.J. KUHNS, R. OBERMEIER, F.J. PRIMUS, U. WESER and M. ZOLTOBROCKI. Springer-Verlag:1985. Pp.163. Hbk ISBN 3-540-15567-8. DM 84.

Progress in Nucleic Acid Research and Molecular Biology, Vol.32. WALDO E. COHN and KIVIE MOLDAVE (eds). Academic:1985. Pp.340. Hbk ISBN 0-12-540032-2. £43.50, \$49.50.

Prostanoids: Pharmacological, Physiological and Clinical Relevance. By P.K. MOORE. Cambridge University Press:1985. Pp.263. Hbk ISBN 0-521-26081-7; pbk ISBN 0-521-27827-9. Hbk £32.50, \$54.50; pbk £12.50, \$19.95.

Protective Effect of BCG in Experimental Tuberculosis. By D.W. SMITH. Karger: 1985. Pp. 97. ISBN 3-8055-4089-2. DM 107, \$38, £22.

The Role of the Registry in Cancer Control. D.M. PARKIN, G. WAGNER and C.S. MUIR (eds). International Agency for Research on Cancer:1985. Pp.155. ISBN 92-832-1166-9. £10.

Serotonin and Microcirculation. Progress in Applied Microcirculation, Vol.10. R.S. RENEMAN and A. BOLLINGER (eds). Karger: 1986. Pp. 92. Hbk ISBN 3-8055-4163-5. SwFr. 66, DM 79, £20, 70, \$28.25.

Survey of Drug Research in Immunologic Disease. Vol.6. Noncondensed Aromatic Derivatives. By V. ST. GEORGIEV. Karger: 1985. Pp. 586. ISBN 3-8055-3962-2. DM 588, \$208.75.

Synthetic Peptides as Antigens, CIBA FOUNDA-TION SYMPOSIUM 119. Wiley:1986. Pp.307. ISBN 0-471-99838-9, £27.50,

Testicular Cancer. Progress in Clinical and Biological Research, Vol.203. SAAD KHOURY, RENE KUSS. GERALD P. MURPHY, CHRISTIAN CHATELAIN and JAMES P. KARR (eds). Alan R. Liss:1985. Pp. 774. Hbk ISBN 0-8451-5053-7. 175.

Textbook of Adverse Drug Reactions, 3rd Edn. D.M. DAVIES (ed.). Oxford University Press:1986. Pp.814. Hbk ISBN 0-19-261479-7, £75.

The Thorax, Part A. Lung Biology in Health and Disease, Vol.29. CHARIS ROUSSOS and PETER T. MACKLEM (eds). Dekker:1985. Pp.1.616. Part A. Hbk ISBN 0-8247-7299-7. Part B, Hbk ISBN 0-8247-7300-4. £252 (sold only as a set).

TNM-Atlas: Illustrated Guide to the TNM/pTNM-Classification of Malignant Tumour, 2nd Edn. International Union Against Cancer. B. SPIESSL, P. HERMANEK, O. SCHEIBE and G. WAGNER (eds). Springer-Verlag:1985. Pp.269. Pbk ISBN 3-540-13443-3. DM 30.

Transformation Assay of Established Cell Lines: Mechanisms and Application. Proceedings of a Workshop organized by IARC in Collaboration With the US National Cancer Institute and the US Environmental Protection Agency held in Lyon, 15-17 February 1984. T. KAKUNAGA and H. YAMASAKI (eds). International Agency for Research on Cancer, Lyons:1985. Pp.225. Hbk ISBN 92-832-1167-7 Nn.

Trauma of the Middle Ear: Clinical Findings, Postmortem Observations and Results of Experimental Studies, By M. STROHM. Karger: 1986. Pp. 254. Hbk ISBN 3-8055-4087-6. SwFr 174, DM 208, £54.40, \$74.25.

Trends in Autonomic Pharmacology, Vol.3. STAN-LEY KAISNER (ed.). Taylor & Francis:1985. Pp.366. Hbk ISBN 0-85066-327-X. £45.

Tropical Disease Research, Seventh Programme Report (1 January 1983–31 December 1984. UNDP/ WORLD BANK/WHO. World Health Organization: 1985. Pp. 272. Pbk ISBN 92-4-156085-1. SFr 45

Archaeology

Evolutionary Case Histories from the Fossil Record. Special Papers in Palaeontology, No.33. J.C.W. COPE and P.W. SKELTON (eds). The Palaeontological Association, London, UK:1985. Pp.202. Pbk ISBN 0038-6804. £30.

L'Environnement au Temps de la Prehistoire. By J. RENAULT-MISKOVSKY. Masson:1985. Pp.184. Pbk ISBN 2-225-80536-9. F 160.

Preserving Field Records: Archival Techniques for Archaeologists and Anthropologists. By MARY-ANNE KENWORTHY, ELEANOR M. KING, MARY ELIZABETH RUWELL and TRUDY VAN HOUTEN. The University Museum, University of Pennsylvania:1985. Pp.102. Pbk ISBN 0-934718-72-5. Np.

Quaternary Evolution of the Great Lakes. P.F. KARROW and P.E. CALKIN (eds). Geological Association of Canada:1985. Pp.258. Hbk ISBN 919216-29-3. \$42 (Canadian).

General

Advances in Heat Transfer. JAMES P. HART-NETT and THOMAS F. IRVINE Jr (eds). Academic:1985. Pp.360. Hbk ISBN 0-12-020017-1. \$79.00

Atti della Società Toscana di Scienza Naturali Residente in Pisa, Serie A (1984). Grafiche Pacini Editore:1985. Pp.264. Pbk np.

No other medium combines such high selectivity with such versatility. MinoRPC is unparalleled. It is optimised to give you fast, high resolution results.

To ensure high reproducibility, we have developed a special synthesis. You can always rely on MinoRPC to be the same every time we make it; every time you use it. And for that extra efficiency and reproducibility, you can work at elevated temperatures, carefully controlled by the Pharmacia high performance Column Heater.

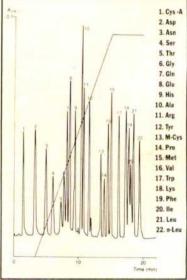

MinoRPC reflects the high standard you've come to expect from Pharmacia. Our contribution to high performance liquid chromatography has already brought success to thousands of chromatographers.

Share the success. Contact your local Pharmacia representative for more information on columns prepacked with MinoRPC.

WHY WOULD ANYBODY **WANTAN** ANTIBODY?

For a wide variety of reasons: Today, monoclonal antibodies can be used as aids to purification. diagnostic reagents, cell surface probes... the list grows for these most versatile of molecules. As a group, they represent one of the

most purified proteins in the world today.

Protein A-Sepharose® CL-4B provides the almost universal chromatographic method to purify monoclonal antibodies, a fact that is comforting after the inevitable investment in time necessary to produce them. It is fortunate that, for such a diverse representative or, should you require it, group of molecules, they are relatively easy ask for further information. In addition to to purify.

As soon as Pharmacia recognised the importance of Protein A specificity for antibodies, we utilised it in an affinity chromatography matrix; using our knowledge to give you success with confidence.

PROTEIN A, TO LEFT OF PICTURE, INTERACTING WITH THE Fc PORTION OF AN IEG MOLECULE, THE HINGE REGION IS CLEARLY VISIBLE. THREE DIMENSIONAL COMPUTER MODEL DERIVED USING FRODO SOFTWARE (T. ALWYN JONES) AND BASED ON X-RAY CRYSTALLOGRAPHY DATA (J. DEISENHOFER, BIOCHEMISTRY 20, 1981, 2361-2370) SUPPLIED BY THE PROTEIN DATA BANK.

Confidence in a product attested by thousands of researchers. Confidence in a product that comes from the biggest manufacturer of affinity chromatography media in the world.

GUIDE TO AUTHORS

Authors should be aware of the diversity of Nature's readership and should strive to be as widely under stood as possible

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclussions are of general interest or which represent substantial advances of understanding. The text should not exceed 3.000 words and six displayed items (file gures olus tables). The article should include an italic heading of about 50 words.

Letters to Nature are ordinarily 1,000 words long with no more than four displayed items. The first page graph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are

Matters arising are brief comments (up to 500 words) on articles and letters recently published in Nature. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted

Manuscripts may be submitted either to London or Washington, Manuscripts should be typed (dead)le spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the World List of Scientific Periodicals fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be eited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpulslished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork tand one conv of the manuscript) will be returned when manusscripts cannot be published.

Important: Manuscripts or proofs sent by air courses should be declared as "manuscripts" and "value \$5" 30 prevent the imposition of Customs duty and Value Added Tax in the United Kingdom.

Requests for permission to reproduce material tradition Nature should be accompanied by a self-addresself tund, in the case of the United Kingdom and United States, stamped) envelope,

Why YOU should become a personal subscriber to Nature in 1986

There will never be a better opportunity than now to take advantage of our personal subscription scheme.... offering direct delivery to your home or to vour place of work at HALF PRICE!

Consider the convenience of having your own personal copy delivered each week carrying crucial research results, news and job opportunities in your specific field HOT OFF THE PRESS! When Nature is such a vital ingredient in your scientific career a subscription is a very small investment to make – in fact the cost works out at less than your daily newspaper.

All you need to do to subscribe is fill in the form below and send it with your personal payment FREEPOST to our offices in Basingstoke. You'll receive your first copy within four to six weeks of your order and thereafter weekly for a year. We *quarantee* that when we invite you to renew your subscription it will be at the lowest rate available.

NATURE VOL. 322 21 AUGUST 1986

671

Can there be an end to spying?

Public espionage, a prolific source of scandal this year, is a serious cause of international friction, a restraint on good relations and even a perversion of national civility. Can it be restrained?

Spies and the public agencies employing them seem to be half way through another bad year. In the United States, a rash of prosecutions of ex-servicemen and ex-agents has made plain the uncomfortable if unsurprising truth that, in a market economy, even loyalty has a price. There has been particular chagrin in the United States at the revelation, unconvincingly disputed, that even the Israeli government has spent resources (from the US military aid budget?) keeping tabs on the government which is its own chief political and economic supporter. The United States has also found itself alternatively able to boast of a harvest of counter-intelligence information gathered from defectors and then embarrassed by the discovery that defectors can defect back again. This painful double and even triple dealing, unfamiliar in the United States, is well-known in Western Europe, where 1986 (so far) has seen yet another eastern intelligence network unmasked in West Germany, the usual crop of expulsions of Soviet diplomats from western capitals (followed by retaliatory expulsions from Moscow) and a general reinforcement of the sense that secrets are no longer safe, whatever they may be. Spies, and their employers, must be asking whether their game is still worth playing.

The issue is further sharpened by the latest twist in the long saga of double-espionage in Britain, a matter of public record since the defection of two Foreign Office officials to the Soviet Union in the 1950s, in circumstances suggesting a tip-off from a sympathizer in counter-intelligence. Who might that have been? The first candidate to come to light was Mr Kim Philby, off and on employed as a British spy, who was recognized (after his disappearance to Moscow in the 1960s) to have been a Soviet agent as well. A second is Sir Anthony Blunt, himself a one-time member of British intelligence, afterwards curator of the Royal family's art collection, who was discovered to have recruited Philby as a double agent and who was stripped of his knighthood a short while before his death. A third is Sir Christopher Hollis, who was for several years the head of one half of the British intelligence network, that called MI5, and who is now (after his death) accused of having been another double agent. One result is yet another bout of speculation about the motives of those who become spies, the supposedly special motives of those who become double spies and the efficiency of the services which employ them.

Moles

The latest most bizarre development concerns Hollis and related matters. In 1981, the British prime minister, Mrs Margaret Thatcher, said that the accusations that he was a double agent had been considered and that they could not be sustained. But, last week, lawyers representing the British government before an Australian court which is being asked to restrain publication of a book by a British ex-agent, said they were prepared to acknowledge, for the purposes of that hearing only, the truth of the allegations against Hollis. (The British courts have already given the government an injunction preventing two British newspapers from serializing the disputed book and even from reporting its allegations.) The strategem will have the effect of concentrating the court's deliberations on the claim that publica-

tion would be a breach of confidentiality, but it is bound to sound like a version of that confusing lawyers' doublespeak typified by the defence of a person against a murder charge which asserts that the defendant acted out of self-defence and was, in any case, elsewhere at the time.

Whatever happens in the Australian courts, the British government is bound to find itself under further pressure to tell more when the British Parliament reassembles in October. The position that the validity of the allegations is irrelevant to the trial is legitimate enough, but it will be interesting to see whether the British government's lawyers can persuade an Australian court that a breach of its contractual relationship with an exemployee can damage the Australian national interest. Meanwhile, the government's critics might usefully use the interval to clarify their complaint: is it the narrow complaint that the government (retrospectively) is incompetent in having allowed its intelligence services to be riddled with double agents or that, these days, there should be more intelligent ways of conducting these affairs?

Vanity

Double agents, whatever their motives, are an inescapable part of the spy business. Those who doubt that should read an account of the mismanagement of the British Special Operations Executive (SOE), a secret organization set up in Germanoccupied France in 1940, which has been contributed to Intelligence Quarterly (a London-based newsletter) by one James Rusbridger, himself an ex-agent. SOE and its doings has become part of the mock-heroic folklore of British exploits during the Second World War. The chief objective was to help organize indigenous resistance to the occupation, but SOE was put together hurriedly, amateurishly and in a way that guaranteed that German intelligence would know what was afoot. One especially damaging double agent, according to Rusbridger, was a Frenchman called Dericourt who was from September 1942 both SOE's Paris agent for the transport of people into and out of France and a regular confidant of the German counterintelligence agencies. When members of the SOE network were being arrested by the score (usually to be executed), how was Dericourt allowed to carry on? Rusbridger's arresting explanation is that his immediate boss in London, parachuted into France with a radio operator to discover what had gone wrong with the network's security, was warned by Dericourt that he would be arrested at a planned rendezvous and so sent his operator to the assignment and to a predictable death. The guilf engendered ensured safe conduct for the French double agent in the damaging months that followed.

What this unheroic tale shows is that all kinds of venality can contribute to the recruitment of agents and double agents and to their survival. But that does not explain the rash of double agents with which the professional intelligence services have been afflicted in the past half-century. Why have so many talented people chosen this tortured and, for some, disastrous way of earning a living? Part of the explanation is that given by Mr Andrew Sinclair earlier this year (see William Cooper's review in *Nature* 322, 317; 1986); now-unfashionable intellectual

coteries (in this case, the Cambridge-based "society of the apostles") may engender that blend of vanity and arrogance that tempts people to believe they can mould the course of history by the secret exercise of their own wits. But in reality it is a shabby business, not merely damaging for those concerned when they are found out and for those whom they betray meanwhile, but for the conduct of normal relations between intellectual communities throughout the world.

The ubiquity of the spy has become an abomination. In many parts of the world, scientists and other intellectuals are habitually supposed to be potential agents when they travel abroad—and may be suspected of potential treason when they return. Who knows how much of the present fragmentation between East and West of the science enterprise derives from the brooding suspicion of the intelligence agencies, vulnerable though they are themselves to infiltration, of the movement of people from one place to another?

That is merely one of the reasons why the time has come to put intelligence-gathering on a proper footing. Another, perhaps even more urgent, is that the repeated discovery of espionage networks in different places is a constant source of sourness in international relations. That intelligence services from time to time embark deliberately on subversive and even criminal activities, and must otherwise operate in some degree outside the normal rules of public accountability, is especially offensive. That many advanced societies must now put up with the indignity of self-imposed self-surveillance by telephone tapping and other such means is another part of the price that everybody pays for the dubious luxury of sustaining espionage. What can possibly be done to restrain not so much the curiosity of governments about what others do (which is legitimate), but the means by which they seek to satisfy that curiosity?

The best hope of progress must be technical, based on the use of electronic means of monitoring and analysing other people's electronic messages. This is the chief function of the National Security Agency in the United States and the General Communications Headquarters (GCHQ) in Britain, which in principle offer a means of learning about the military capabilities of other governments without requiring that people elsewhere should be actively disloyal. Is it entirely out of court that the major espionage governments should agree among themselves to rely on devices such as these wherever possible? (The fact that even organizations such as GCHQ may be penetrated by spies, as has been spectacularly demonstrated in Britain, is probably not nearly as relevant as it seems; those with secrets to hide should be able to guess which are at risk from listening posts and should plan accordingly.) Economic and political secrets, also common objectives of intelligence agencies, are less easily accessible to electronic surveillance, but are much more often within reach of an intelligent reading of other people's newspapers than the intelligence community would like to think. The underlying fallacy of much of what the intelligence services get up to is the assumption that each marginal element of information is almost priceless. Especially when the price already being paid includes a large element of self-imposed illiberality, this cannot be the case

But an agreement to restrain mutual curiosity, even if it were a formal convention, would hardly be sufficient by itself. Why not go further, and amend the Vienna Convention that regulates the use made of diplomatic missions in such a way as to deprive diplomats found guilty of espionage of the immunity from prosecution which they enjoy at present? There would be obvious difficulties is getting governments to agree that their nationals should be tried under other national laws, which vary enormously both in what they require as evidence and in penalties they impose, but it should not be beyond the wit of well-intended people to develop a system of international criminal law to meet the need for an effective stick to beat the spies. The carrot, of course, is the benefit of the civility that would follow for the rest of us.

Chernobyl made plain

This is what the Soviet Union should say next week about the Chernobyl accident, and why.

NEXT week, there will be a gathering in Vienna, under the auspices of the International Atomic Energy Agency, to discuss the report prepared by the Soviet Union on the reasons for the accident at the Chernobyl reactor at the end of April. Only the sketchiest information about the Soviet document is as yet available (see opposite), and is certainly not sufficient in itself to satisfy legitimate curiosity elsewhere about the accident and its consequences. The chances are that even the full report will not do that: most official statements hurriedly put together leave unanswered questions that are best dealt with in the kinds of technical discussions arranged for next week, and in which the Soviet Union has agreed to take part. So far, so good.

That there is a legitimate curiosity in what happened at Chernobyl may seem to many in the Soviet Union to beg the question of the right by which people elsewhere inquire into strictly domestic matters, such as the arrangements for generating electricity. The simple answer, that the Chernobyl accident polluted the territory of other nations, is only part of the reason why some kind of explanation must be forthcoming, and by itself only requires from the Soviet Union an estimate of the amount and composition of the radioactivity released, an attempt to agree on estimates of the damage that may have been done with those affected and, if appropriate, an undertaking that there would be negotiations about compensation. Nothing has been heard, as vet, about formal demands for compensation, which would have to be raised through diplomatic channels by the governments believing themselves to have been injured, not at technical meetings such as that planned for next week. Meanwhile, the Soviet Union has implicitly acknowledged a wider legitimate interest in Chernobyl by its agreement to appear in Vienna.

A second explanation, but equally insufficient, for the Soviet decision to say more than the bare minimum is the need to head off future trouble with now-nervous neighbours. Long before the accident, there were protests about the siting of reactors near the borders between France and Belgium and between Czechoslovakia and Austria. So far, there has been relatively little complaint about Soviet reactor policy from the countries most at risk, those of the Warsaw Pact in Eastern Europe, but that may require special explanation. It is common prudence to take whatever steps are possible to anticipate and counter such anxieties. But the Soviet Union has gone further by agreeing to participate at Vienna and by doing some homework in advance.

What else can the world legitimately ask of the Soviet Union? Because even the Chernobyl accident might have been worse, people elsewhere have a right to be assured that the management of these complicated machines is conducted with the zealous regard for worked-out procedures which is the nuclear industry's standard boast on its own behalf. As things are shaping up, the Soviet Union plainly intends to meet this demand indirectly, by using an account of how laid-down procedures were not followed to suggest that the same need never happen again. But such an account will not suffice. Inevitably, and properly, questions will be raised at Vienna about the arrangements now in place for regulating the use of nuclear reactors. By what means are matters like this decided? Who are the people concerned? These will be painful questions for the Soviet Union to answer, but they cannot easily be ducked. Beyond them are the even larger issues in which external curiosity is legitimate: what can be gleaned over the years about the effects of radiation on people exposed to excessive doses of it? And what, in any case, is being done to safeguard or even monitor those at risk? There is no requirement in international law that one country must account to others for its care of its own people, but these exceptional circumstances require concessions even in that direction.

Official Chernobyl report

Timetable for a reactor disaster begins to emerge

THE Soviet report on the Chernobyl reactor accident, distributed to the Vienna delegations to the International Atomic Energy Agency last week, is said by those who have read it to be strong on details of the reactor design but thin on details of how the accident happened. But the sequence of events leading to the accident. and more details of the "unauthorized experiment" said to have been under way on 25-26 April, have emerged.

For the first time since the accident, there are suggestions in the Soviet document that the RBMK reactor design is not fault-free. Thus the report suggests that existing reactors of this type should be modified by means of longer control rods, 2.4 per cent uranium enrichment (now 2.0 per cent) and extra reactor sensors even if these measures "degrade the economics" of the reactor type.

The report is intended as the basis for a discussion of the accident to be held at Vienna next week. The confusion attending its appearance stems from what appears to have been a Soviet requirement that the agency itself should distribute the report to national delegations only, but allowing national delegations to deal with the document (382 pages of Russian text) as they see fit.

Other information about the content of the report has appeared in Sweden and from the Atomic Industrial Forum of the United States which on Monday this week released a brief summary of the sequence of events leading to the accident. The forum said that "at first glance... the report appears to be complete and frank".

According to a report in the Japanese newspapers Asahi Shimbun, the "experiment" was intended to determine the amount of energy that might be recovered from a spinning electrical generating set and the coupled steam turbine after the steam input had been disconnected. According to this account, more than one assessment of this kind was planned, using the generating set at Chernobyl called Number 7 and for this reason, the reactor providing steam for the generator was not shut down. However, the system that would have caused the reactor to shut down of its own accord was disabled.

One of the difficulties in reconstructing the course of events at Chernobyl reactor Number 4 appears to have been that the data-recording system used for monitoring normal operations had been switched to the monitoring of the electrical test. with the result that capacity for the recording of reactor data had been preempted. As a consequence, the sequence of events has had to be inferred from a mathematical model of the reactor.

The sequence of events began roughly 24 hours before the first release of radioactivity, at 01:00 local time on 25 April. when steps were taken to reduce the operating power of the reactor. Twelve hours later, at 13.05, the Number 7 turbine generator was disconnected from the system, but its electrical output switched to turbine Number 8. These are two generating sets handling the thermal outputs of the damaged reactor, Number 4 out of four completed reactors at the site.

The rate at which the speed of the Number 7 generating set would have declined would have been determined by the magnitude of the external electrical load. The emergency cooling system was disabled at 14.00 on 25 April, but the report says that the control room explicitly instructed that the reactor should continue

When instabilities appeared, two extra pumps were added to the water-cooling circuit some three and seven minutes respectively after 01.00 on 26 April, but the Soviet document says that the reactivity of the reactor had reached the point, at 01.22, at which the reactor should immediately have been shut down. In the event, the reports say, the operators persisted with their experiments on the turbines, including the closing of the stop control valve of turbine Number 8 four seconds after 01.23 on 26 April.

Within half a minute, the accounts continue, the reactor began to generate more power, and the operatives sought to close it down by means of the control rods. But in the event, the full entry of the rods was prevented by an explosion. A witness is reported as saying that he heard two loud explosions at that time and saw a fireball

scattering sparks on the roof.

The Soviet report outlines a series of errors in safety procedures of which the reactor staff were guilty, including the disablement of all but six or eight of the control rods with which the reactor is equipped, and the disablement of the power control system that would normally maintain the power output near that for which the machine was designed. The result is that control of the reactor would have been more difficult. The decision to disable the automatic shut-down system for the reactor would have made it necessary to use manual procedures for controlling the power output in case of an emer-

One of the puzzling features of the report is the statement that, after the explosions, the temperature of the uranium fuel increased to between 1,600 and 1,800 °C, hot enough to volatilize some fission products but not enough to vapourize the refractory components of the fuel. But that step could be the one that apparently led to the further release of radioactivity on 29 April.

Environmental research

Making the most of Chernobyl

BRITISH scientists are hoping that a £1 million package of research projects can be put together to seize the scientific opportunities presented by the Chernobyl nuclear accident. Radionuclides were released into the atmosphere on a scale that would never be contemplated experimentally, giving a unique chance to study their pathways in the environment.

An expert committee organized by the Natural Environment Research Council, the Coordinating Group on Environmental Radioactivity, hopes to include researchers from government departments, the universities, the Central Electricity Generating Board, British Nuclear Fuels and the Meteorological Office in an integrated programme. Much of the information gained would be of direct benefit for it would aid understanding of the consequences of other accidental releases of radioactive material.

Studies carried out so far already reveal a few surprises. Radionuclides are much "stickier" than expected; once deposited on vegetation they are not quickly washed into the soil. Thunderstorms, triggered as warm, moist air containing the plume of fall-out, prove to be particularly effective in washing radionuclides out of the atmosphere (see p.690 of this issue). These topics will be studied further: others needing attention are the overall pattern of deposition, which is highly heterogenous; the storage of radionuclides in snow and their release on melting; and whether the radionuclide pulse will confuse other studies on radionuclides in the environment.

Any programme would best be integrated with an overall European effort. Already attempts are under way for collaboration within the European Economic Community and it is possible that some money might be found from the European Commission. Otherwise national programmes will have to be tied together and funds for the British part must come from other programmes - there is little chance of extra money being granted in present political circumstances. Alun Anderson

Rocket launchers

Japan enters the space race

AFTER the successful launch of the H-I rocket last week, Japan's rocket experts are bursting with confidence. For now nothing seems to stand in the way of Japan entering the commercial satellite launching business in the 1990's — nothing, except perhaps a small group of tuna fishermen.

The two-stage H-I rocket blasted off from the National Space Development Agency (NASDA)'s space centre on Tanegashima island southwest of Kyushu at 5.45 am on 13 August. About 4 minutes later, the domestically-built cryogenic second-stage engine burst into life boosting the launcher into an eliptical orbit 1,500 km above the Pacific. Coasting over South America about 50 minutes later, the second-stage reignited for a brief 20-second burn that transfered the launcher to a circular orbit before release of first the Experimental Geodetic later named (Hydrangea), and then the Japan Amateur Satellite-1, christened "Fuji" (Wisteria).

News that radiowaves from Fuji had been received in Chile was greeted with shouts of "banzai" at the headquarters of the Japan Amateur Radio League whose members have invested 5 years and 120 million ven (£0.5 million) in building Japan's first ham radio satellite. It is only to be hoped that Japan's 720,000 ham enthusiasts do not overtax the little 50 kg satellite. Takeshi Saito, the league's amateur satellite committee chairman remembers with embarassment an incident three years ago when Japanese hams jammed the frequency band for communication with the US space shuttle Columbia and then vented their frustration by trading abuses such as "bakayaro!" - meaning "you idiot"

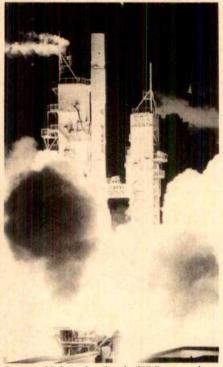

Equipped with 10 channels for analog communications and four for digital, Fuji comes over the Japanese archipelago six times a day permitting communications for about 10 minutes each time. A digital relay allows storage of messages which can be retransmitted on the other side of the Earth.

Ajisai, a 2-m diameter mirror ball to be used for triangulation surveys was also successfully put into orbit alongside Fuji. But the real hero of the day was the H-I rocket itself.

The LE5 second-stage cryogenic engine developed by NASDA at a cost of 44 billion yen (£192 million) performed flawlessly, as did the Japanese-built inertial guidance system. And in a spectacular finale five hours into orbit, the LE5 released a burst of liquid hydrogen fuel over the eastern United States, prompting reports of UFOs and exploding

satellites. This is the first time the US has found itself downrange of a nation with cryogenic launchers, and may be an omen of things to come.

Japan can now forge ahead with development of the bigger H-II which is scheduled for completion in 1991 and will be entirely made in Japan. The stage will then be set for Japan to enter the commercial market for satellite launchers. But will NASDA be able to increase launch frequency at its Tanegashima

Last week's launch utilized a US first stage but a Japanese cryogenic second stage.

Space Centre to meet the demands of foreign users?

The waters off Tanegashima teem with tuna, and under an agreement with the local fishing cooperative NASDA can only launch rockets during 90 days of the year, 45 days in summer and 45 in winter. This effectively limits NASDA to two launches a year, and for "compensation" NASDA annually pays the fishermen 600 million yen (£2.6 million). This is over and above the 1,300 million yen reputedly paid to the fishermen when the launch site was first built.

The only inconvenience to fishermen is that during the launch a 300 km² area of ocean extending about 30 km downrange of the launch site is closed to shipping. But fishing cooperatives in Japan, like other rural groups loyal to the ruling Liberal Democratic Party, have considerable political power. And if NASDA wishes to increase launch frequency in the 1990s, the local fishermen will have the final say.

US space policy

No business for new shuttle

Washington

PRESIDENT Reagan last week ended months of uncertainty over the future of the US space programme by telling the National Aeronautics and Space Administration (NASA) to build another space shuttle orbiter to replace Challenger, thus restoring the size of the shuttle fleet to four. Reagan also signalled a major policy turnaround by saying that NASA would not in future be allowed to compete with the private sector to launch commercial satellites on the shuttle, but would instead concentrate on military and research payloads. The announcement marks the end of the policy of trying to make the shuttle commercially viable.

Senior administration officials have for some months been divided over how a replacement shuttle would be paid for, and last week's announcement from the White House did little to clarify where the required \$2,800 million will be found. The White House plans to ask Congress for \$2,350 million in extra budget authority for NASA over the next 5 years, using in part "unspent funds" from other government agencies. But it is unclear to what extent NASA's other programmes will be affected. Some additional belt-tightening at the agency seems a possibility, although Reagan renewed his commitment to build a space station.

The replacement shuttle will incorporate several improvements to the existing models. New brakes, engines and computer systems were mentioned, as well as other possible safety improvements recommended by the Rogers commission into the *Challenger* accident. The new orbiter is not expected to be completed until 1991.

Of the 44 commercial satellites NASA is already contracted to launch aboard the shuttle, only 16 will be launched by NASA before 1992. The remainder may be shifted back to commercial unmanned launch vehicles. But because it has been US policy to rely on the space shuttle as the nation's main launch system, US aerospace manufacturers have been unwilling to get into the private launching business, and even if there is now a scramble to manufacture new commercial launchers - which some doubt - many of the payloads that might have flown on the shuttle seem destined to be launched by foreign commercial services. Besides the French Ariane rockets, which are booked up for the next several years, both China and Japan have embryonic launching services that may take a significant proportion of the backlog of satellites now waiting to be launched. **Tim Beardsley** UK research

Call for more open councils

REFORM of Britain's research councils is called for in a new report from a body representing more than two-thirds of university teaching and research staff. The Association of University Teachers (AUT) wants to see more open research councils among a host of other changes it claims are necessary to deal with the "crisis" in university research.

The crisis is attributed to the breakdown of the dual-funding system. Although the universities carry out more than half of all basic research in the United Kindgom, the budget supplied through the University Grants Committee (UGC) (to maintain "well-founded" laboratories) and the five research councils (to support research projects) has declined in real terms while the costs of research are rising rapidly. Increasing numbers of researchers are joining the brain drain; libraries have had to cut back book purchases by 40 per cent since the 1970s; the student/staff ratio has deteriorated; and an increasing percentage of researchers face an uncertain life on short-term contracts.

The fight put up by UGC and the research councils to try to remedy matters seems not to have impressed AUT. UGC's new policy of trying to assess the quality of research carried out at different university departments and to concentrate scarce resources at those rated highly is seen as exacerbating the effects of the cuts and is "emphatically rejected". Selectivity, the report says, favours those areas in which short-term returns can be easily identified while university research should be of the "fundamental kind" from which "major breakthroughs rather than marginal advances result". The effect of selectivity may undermine university autonomy and create a hierarchy of universities.

The five research councils come in for some criticism. Their "success. . . in predicting growth areas in research has not been great", the report says. The councils are appointed by the Secretary of State but AUT believe they should be more directly representative of scientists. Nominations to the councils and their committees should be by learned societies and regular open meetings held to discuss priorities in research funding. Particular difficulties now arise because not all research proposals rated "alpha" (to be funded "at all costs") by peer review can now be funded. In that sense the report says "peer review has broken down" and personal views may be substituted. Safeguards to ensure that committee members do not receive preferential treatment, and full explanations of all decisions, including the reasons for choices between applicants, given publicly, are called for.

The Advisory Board for the Research

Councils (ABRC) could also be made more open, the report says. Each year, in its advice to government, the board has protested more strongly about the parlous condition of the universities. But the government shows little sign of listening. To add clout the report suggests that Parliament be given the right to discuss the advice of ABRC and to cross-question it. Whether this could be done without changing ABRC's status is not yet clear.

An additional body is needed as a national forum to discuss research and development policy. The National Economic Development Council, an organization with representation from government, industry and unions, would be suitable.

British industry is seen as needing encouragement to commission research in the universities: there is evidence that foreign industrial investment in British universities exceeds that of British companies. Changes in tax-exemption rules and the establishment of a fund to help small firms sponsor university research are possible solutions.

Creation science

Nobel laureates go into battle

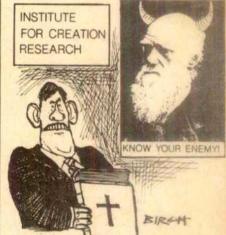

Washington

SEVENTY-TWO US Nobel laureates have signed a brief filed with the Supreme Court this week urging the court to declare unconstitutional a Louisiana law requiring balanced treatment of evolution and creation in state schools. According to organizers of the brief, this is the largest group of Nobel laureates ever to sign a single document.

The Supreme Court agreed in May to hear arguments on the constitutionality of the Lousiana statute. In 1982, a federal district court struck down a similar Arkansas law because definitions in the law made it clear that creation science was directly derived from descriptions of creation in the Bible. The Louisiana statute removed the specific definitions of what creation science is, leaving only the tautology that creation science means "the scientific evidences [sic] for creation". The Nobel laureates' brief sets out to show that the Louisiana statute originally included language similar to the Arkansas statute. but lawmakers altered it after the Arkansas decision. The brief further attacks the law for singling out evolution as a theory. rather than emphasizing the uniformly tentative nature of science and argues that by creating a distinction between scientific

Murray Gell-Mann, one of the laureates leading the fight against the "forces of darkness".

fact and evolutionary theory, the statute implicitly tells schoolchildren that "while most of what they learn in science class is 'proven scientific fact', evolution is not".

Murray Gell-Mann, who won the Nobel prize for physics in 1969, says it is not just biological science that has come under attack from creationists. Gell-Mann feels the Lousiana act represents a "grave danger to the Republic," one that will result in a decreased ability of schoolchildren to deal with scientific issues. Francisco Ayala, director of the Institute of Ecology at the University of California at Davis and a member of the National Academy of Sciences committee on science and creationism, agrees that nothing less than the "survival of rationality in this country's schools" is at stake. The Academy is preparing its own brief. Duana Gish, vicepresident of the Institute for Creation Research (ICR), says his organization has not taken a position on the Supreme Court

The Supreme Court will hear oral arguments in the case sometime late this year or early next. Frank Press, president of the National Academy of Sciences says the debate should not be taken lightly. According to Gell-Mann, it is the "old struggle of science against the forces of darkness".

Price-Anderson Act

Regulatory bill goes critical

Washington

AFTER months of hearings, meetings in smoke-filled rooms and political threats and counter-threats, Congress appears ready to extend the Price-Anderson Act. Due to expire next year, Price-Anderson establishes limits on the financial liability of commercial nuclear power plant owners in the event of an accident. With four different versions of the legislation currently floating around Congress, there still must be a lot of horse trading before a bill is passed. What finally emerges will go a long way towards determining the future of nuclear power in the United States.

The Price-Anderson Act, enacted into law in 1957, offered government indemnification to protect the fledgling nuclear power industry from financial losses resulting from a power plant accident. In its original form, Price-Anderson required utilities to insure themselves to the maximum amount commercially available then \$60 million — and the government to provide indemnification for an additional \$500 million. In 1975, Congress modified the act, making utilities liable up to a fixed limit for claims not covered by their insurance. A \$5 million "retroactive premium" can be levied against utilities for each of their plants in the event of an accident. A key feature of the scheme is its "no-fault" provisions. Utilities will be liable collectively, regardless of which of them is at fault in an accident.

Today, with 101 operating plants and \$160 million in commercial insurance available, the total compensation to vic-

tims of a nuclear accident is \$665 million. The only real test of Price-Anderson was the accident at Three Mile Island, all claims related to which were settled out of the utility's commercial insurance cover.

A recent report* by the General Accounting Office (GAO) estimates that a \$665 million liability limit would be sufficient to settle claims related to a catastrophic accident for only 4 per cent of existing reactors. Even staunch supporters of Price-Anderson admit that the \$665 million figure is now unrealistically low. What the industry dreaded is that a new version of Price-Anderson would remove liability caps. But unlimited liability, vigorously supported by environmental groups, was shot down earlier this month when its principal congressional proponent, Senator Robert Stafford (Republican, Vermont) agreed to accept a realtively high, but fixed, limit on liability.

Current versions of the bills extending Price-Anderson vary widely in their liability limits. At one end of the spectrum, a bill sponsored by Representative Morris Udall (Democrat, Arizona) calls for retroactive premium payments of up to \$63million per reactor per accident, limiting payments in a single year to \$10 million. The Udall bill also requires utilities to carry a minimum of \$200 million worth of insurance for each reactor, bringing the total liability limit for an accident to \$6,563 million. According to GAO calculations, this limit would be adequate to give full compensation for a catastrophic accident at 95 per cent of power plants. At the other end of the spectrum, a bill reported from the Senate Committee on Energy and Natural Resources calls for a single payment, maximum \$20 million, per reactor per accident, for a total liability limit of \$2,180 million. GAO concludes that 64 per cent of reactors would be covered by this limit. The current prevailing view is that a cap in the region of \$5,400 will emerge in the final bill.

Industry reaction to the proposed changes in Price-Anderson is curiously mixed. Although industry may be forced to accept liability limits higher than it would like, the nuclear lobby appears to have prevailed on many aspects of its agenda. Environmental groups had sought changes in the law that would allow utilities to sue for recovery of their retroactive premiums from a negligent plant operator where an accident occurred. Keike Kehoe, director of the nuclear accountability and insurance project at the Environmental Policy Institute, says this would bring financial accountability to the industry, encouraging high safety standards to avoid huge financial losses. The industry position is likely to prevail.

Environmental groups are bitterly disappointed by the direction renewals are taking. Kehoe points out that in a 1983 report to Congress the Nuclear Regulatory Commission recommended shifting the full costs of a catastrophic nuclear accident to utilities, a position it has since backed away from. But Kehoe believes without unlimited liability, victims of a nuclear power plant accident may never receive fair compensation. Kehoe says the industry can provide \$10 million per year for as long as it takes to settle all claims. She points out that the industry is already committed to spending around \$5 million a year in insurance for each plant.

One contentious provision of proposed Price—Anderson extensions that could ultimately torpedo the bill's chances is indemnification of the government's own nuclear activities. Under current law, non-defence government nuclear activities have a \$500 million limit on liability. In some versions of the new legislation these liability limits would be removed entirely, both for nuclear plant activities and for nuclear waste activities.

If Price-Anderson is allowed to expire, all currently licensed nuclear plants would continue to be covered under existing law, meaning that liability would only rise slowly from its current \$665 million level as plants under construction come on-line. But without an extension to Price-Anderson, the next generation of power plants will face the prospect of unlimited liability. The industry says that means they simply would never be built.

Joseph Palca

Change of priorities in French science

SUPPORT for basic research in France will be little changed next year, in real terms, from 1985, the last full year of the previous socialist administration, according to unofficial figures published by the newspaper Le Monde. But direct government aid for industrial research will be cut.

The level of support comes nowhere near that foreseen in the three-year research plan for which the French National Assembly voted last December. That would have given by 1987 some 8 per cent real growth in research budgets, and 2,800 new posts for scientists and technicians. The Le Monde report foresees just 280 new research posts and 500 technicians, engineers and administrators are to be sacked or not replaced.

The special funds of the ministry of research (spent directly in industry or government and university laboratories, rather than through research councils on applied topics) will also fall from FF1,200 million (£120 million) in 1985 to FF750

million in 1987. The new government is apparently not convinced that ministry research judgements, at least on the previous scale, are better than industry's own. ANVAR, the government agency promoting research in small and medium-sized industries, including the thousands of companies making up France's agro-food sector, can also expect to lose 30 per cent of its funds.

Senior government advisers appointed by the previous administration and still in post, do not think the new government has abandoned industry, however. They expect new tax breaks on research and development budgets to be announced. But many doubt whether such fiscal incentives will do much to change the present extreme concentration of French industrial research in a few major companies, or to treat the basic French malaise: poor links between academics and industry caused by traditional divisions in the education system.

*Nuclear Regulation: Financial Consequences of a Nuclear Power Plant Accident (General Accounting Office, Washington DC GAO/RCFD-86-193BR). Israel's water

Down to the very last drop

Rehovot

DESPITE having the most comprehensive water-planning system in the world and a plethora of internationally recognized water experts, Israel is now suffering the worst water shortage in its history. Government officials blame three years of drought, but most scientists blame the officials.

Dr Gerald Stanhill, an agricultural meteorologist at the Ministry of Agriculture's Volcani Centre, says that, statistically, the past three years were not exceptionally dry. Indeed, they fell well within the rainfall values to be expected from the pattern of the past 55 years. Over that period, annual rainfall within the geographical boundaries of Mandatory Palestine (the area controlled by Israel today) averaged eight cubic kilometres, with a standard deviation of 25 per cent. Perhaps, as the cloud seeders claim, seeding operations have somewhat increased rainfall since the late 1960s. However, the statistics certainly show that rainfall has not declined.

"Israel's water crisis is like its money crisis. It has simply drawn more out of its account than has gone into it", Stanhill says. He welcomes the government's decision to cut back water consumption by 10 per cent this year, although he thinks that what is needed is a policy to build up and maintain a national water reserve at a level equal to three years' consumption.

Dr Joseph Shalheveth, acting director of the Volcani Centre and chief scientist at the Ministry of Agriculture, is less alarmed by developments than other scientists. In his view, "the situation is tight but not impossible". If next winter is also dry, however, drastic cutbacks will be required, as they were, he points out, in California seven years ago. In that case, Israel, for some years a net exporter of agricultural products, would become an importer.

Meanwhile, Volcani scientists who are largely responsible for the exceptionally efficient use of water in Israel's agriculture, are looking for new ways of getting more dollars out of every drop. They have successfully introduced mangoes, avocados, spices, medicinal plants and new varieties of flowers. But each has only a limited export market, and all of them together cannot possibly replace waterhungry cotton, now the main cash crop of Israeli farmers.

Nevertheless, cotton acreage is being reduced this year, as an emergency measure by one-third, and some water experts — who point out that it has been grown at a loss in recent seasons — say it should be eliminated completely, even if this clashes with the Zionist dream and

drives thousands of farmers off the land.

Agriculturalists and their supporters are unwilling to write off cotton, pointing out that flowers, export earnings from which went up this year from \$74 million to \$104 million, were cultivated at a loss for some time and have now bounced back.

Advocates of cotton point out that it can be irrigated with sewage water, but this could be potentially dangerous, says Weizmann Institute Professor Mordeckai Magaritz and Daniel Ronen of the Israel Hydrological Service. Irrigation with treated sewage introduces undesirable amounts of pollutants into the soil, and unless comprehensive preventive measures are taken, into the aquifer as well. Magaritz and Ronen would therefore limit the irrigation of cotton with treated sewage to areas such as the semi-arid Negev, where there is practically no danger of polluting important aquifers.

Nechemia Meyers

Fossil bird shakes evolutionary hypotheses

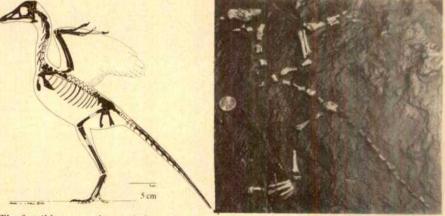

Washington

Fossil, remains claimed to be of two crowsized birds 75 million years older than Archaeopteryx have been found in the 225-million-year old Dockum Formation near Post, Texas. Sankar Chatterjee, a palaeontologist at Texas Tech University, who found the fossils, says they have advanced avian features that place them closer to the ancestor of modern birds than Archaeopteryx and make them possible direct ancestors.

Chatterjee intends to assign the find to a new genus, Protoavis. Among the features that Chatterjee claims identify Protoavis as a bird are elongated forelimbs, temporal fossae confluent with the eye socket, a definite furcula (wishbone), and a plate-like sternum (breastbone) with a small keel. The quadrate is also said to be typically avian. Other avian features are a cnemial crest on the tibia and flight-muscle attachment sites on the humerus. No feather impressions have been found, but Chatterjee claims to see quill nodes on the ulna and hand bones and he believes that Protoavis could fly. Protoavis also has reptilian features: four teeth in the forward part of its jaw, a tail and clawed fingers.

Protoavis seems certain to reopen a longrunning controversy on the evolution of birds, in particular whether the common ancestor of birds and dinosaurs was itself a dinosaur. Protoavis, from the late Triassic, appears at the time of the earliest dinosaurs, and if the identification is upheld it seems likely that it will be used to argue against the view of John Ostrom of Yale University that birds are descended from the dinosaurs. It also tends to confirm what many palaeontologists have long suspected, that Archaeopteryx is not on the direct line to modern birds. It is in some ways more reptilian than Protoavis, and the period between the late Jurassic Archaeopteryx and the worldwide radiation of birds in the Cretaceous has to some seemed suspiciously brief.

Chatterjee's research has for the past six years been supported by the National Geographic Society, which publicized the find last week. The work has yet to be published in a peer-reviewed journal, but two independent palaeontologists (including Ostrom) who have examined Protoavis agree it should probably be classified as a bird. Ostrom stresses, however, that the remains are very fragmentary, and while agreeing with Chatterjee's tentative classification says the case is not finally proven. But Ostrom disagrees with Chatterjee in not seeing even indirect evidence of feathers, saying the bones where quill nodes might be seen are badly preserved, nor does he consider the forelimbs especially elongated. Tim Beardsley

The fossil bones and an artist's reconstruction showing the recovered fossils (dark bones) of the putative Protoavis "bird".

Weapons potential

Defence lobby eyes antimatter

THE US Air Force appears to be taking seriously a report from the Rand Corporation that antimatter might be used as a component of weapons systems. Antimatter packs a tremendous punch, equivalent to some 44 tons of TNT per milligram, when it annihilates with ordinary matter, but until particle physicists began to make and handle antimatter (particularly antiprotons) routinely, any thought of using the material was mere science fiction. But the report, commissioned from Rand, a non-profit US think-tank, by the US Air Force in 1983 and released last year, claims that problems facing the use of antimatter in rocket motors for reversing direction in Earth orbit, beam weapons and the pumping of X-ray lasers could be resolved within five years. Sufficient amounts of antimatter to be militarily "interesting" — some 10 mg a year could be produced within another 15 years if the US government were prepared to spend between \$5,000 and 15,000 million on a development programme.

Basic research on antiproton trapping is already under way at laboratories such as the European Organization for Nuclear Research (CERN) near Geneva. The report says that interaction with basic science could push a military programme forward: "Our position is that the critical experimental work... is so rich with interest and so widespread in the area it intersects that researchers outside existing defense research (as well as those in it) should find it stimulating and an opportunity for creative invention". This interest leads to Rand's "reasonably confident prediction" that five years of research would resolve whether military applications are possible.

But could antimatter, currently produced in only miniscule amounts (some 10^{11} antiprotons per day, or 10^{-8} – 10^{-7} mg per year at CERN, for example) really be collected and used? According to Rand, the production and storage problems will be difficult and complex, and "there can be no confident assertion" that they will be solved. Many handling issues might be solved in experiments on normal matter (such as negative hydrogen ions that simulate the mass and charge of antiprotons) and others with present antiproton production technologies. Antiprotons could be held in static or dynamic electromagnetic traps (for example, Penning traps); at special sites in normal matter (for example in liquid helium bubbles); as spinpolarized antihydrogen; or as condensed antihydrogen in a cryogenic enclosure.

Antimatter has already been stored in minute quantities, and an experiment approved at CERN by a collaboration led by a Los Alamos group could lead to the storage of 10¹¹ antiprotons per cubic centimetre. The main aim of this experiment is the collection and cooling of single antiprotons to measure their weight (do they fall upwards?), but the funding for this part of the experiment has not yet been raised. The rest of the experiment involves antiproton accumulation in a Penning bulk ion storage trap. The experiment has nothing to do with Rand's proposals, a spokesman points out.

Production of sufficient antiprotons to be useful, and the energy costs involved, may be the hardest problem facing weapons designers. Produced by colliding a proton beam to a target, at most one antiproton is collected per 100 incident protons, and this at the highest beam energy in use for the purpose (120 GeV at the Fermi National Accelerator Laboratory near Chicago). Taking into account the energy efficiency of accelerators, and assuming a "difficult near-term improvement" in antiproton collection technology, some 4 GW of external power would be needed to produce the militarily useful amounts of 10 mg of antiprotons a year, the report estimates. This is a huge and expensive power consumption but the gaseous diffusion plants for the separation of uranium isotopes once used in the manufacture of nuclear weapons consumed 6 GW. With the same parameters, antimatter production costs would reach \$133 million per mg. "Some applications" could easily accommodate such costs, the report says.

Antimatter could be used for propulsion, power generation, beam weapons and "classified additional special weapons roles". In propulsion, for example, the annihilation of antihydrogen with hydrogen could produce effective exhaust velocities of 10 km s⁻¹ to a major fraction of the speed of light. Propulsion missions otherwise more or less impossible because of weight of fuel (such as Earth orbit reversal), would become feasible if antimatter were used.

In power generation, antimatter could be used for orbital prime power "for engagement". Antimatter could also help in the design of lightweight beam weapon systems, be used as beams for "hard kills", or help produce the very short energy pulses required in pumping X-ray lasers.

Understanding antimatter would be a "prudent" goal for the US Air Force and worth an investment of \$1 million on basic research as a preliminary study, and if that went well another \$100 million spent on a phase-A (pre-prototype production factory) study. The Air Force appears to have taken this recommendation seriously, and a research programme has begun.

Robert Walgate

Computers thriving from NSF coffers

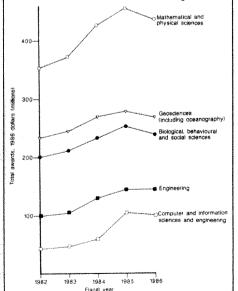

Washington

The total value of research awards by the National Science Foundation (NSF) has increased substantially over the past four years, although some subjects have done much better than others (see below). The graph shows total awards made by each of the foundation's research directorates in constant dollars; retroactive adjustments have been made as necessary to take account of changes in jurisdiction, so that categories are consistent. Average award size by each directorate also increased over the same period.

All directorates' awards increased between 1982 and 1986, but a fall between 1985 and 1986 is evident, caused in part by the effect of Gramm—Rudman budget cuts in the current fiscal year. Much the largest increase was for computer and information sciences and engineering (129 per cent after inflation over the four years). This largely reflects NSF's establishment of five supercomputer centres. The other increases were 45.3 per cent for engineering, 23 per cent for mathematics and physical sciences, 14.4 per cent for geosciences and 21 per cent for biological and social sciences.

The administration proposed an increase again in 1987 for NSF, but Congress may yet baulk at the idea (see *Nature* 322,

487; 1986). NSF's budget proposal for 1988, now ready to go the Office of Management and Budget, will, according to director Erich Bloch, be "highly responsive" to the call of the Packard report ear-

lier this year (*Nature* 321, 372; 1986) for NSF to administer a \$10,000 million 10-year programme to improve university research facilities.

Tim Beardsley

Penguin deaths questioned

SIR-Reports that the penguins in the Falkland Islands are dying on a large scale and that this may be due to competition for food from fishermen or marine pollution¹² seem premature. I happened to be watching birds at sea off the Falklands during the season of the recent rockhopper penguin (Eudyptes chrysocome) mortality in both 1985 and 1986.

Most of the Falkland seabirds appear to benefit greatly from the activities of the fishermen, following their boats in hundreds of thousands to feed on the spilt fish and offal from deep-water species that would not otherwise be available to them. and their populations are obviously flourishing

The penguins are usually difficult to see at sea, but although they frequent the same area along the edge of the continental shelf they do not normally appear to follow the fishing fleets, either because, being unable to fly, they have difficulty in keeping up, or because they appear to feed in roughly equal proportions upon plankton and smaller squid of the genus Teuthowenia' which the fishermen do not appear to catch yet, taking larger fish and squid of the genera Illex and Loligo instead

The main difference between the two years in fact appeared to be that the southern summer of 1986 was unusually hot in the South Atlantic, with the result that among other things there was an influx of warm-water seabirds from the north, and the spring fires intended to remove the dead grass in the Falklands escaped control and burnt in the peat for months over areas of up to 6,000 acres, which one would have thought ought to be of much more concern to local naturalists. More penguins fed inshore than in 1985, possibly because the warm weather affected the growth or accessibility of their food at sea in the way that occurs when the warm current El Niño extends southwards off Peru in the Pacific5.

A few dozen penguin bodies were seen both at sea and on the beaches, with more reported at the breeding colonies, but the number was not large by other standards' for a population estimated at five million breeding birds7.

The main cause for concern appears to be that the huge breeding population on Campbell Island, formerly the largest in the South Pacific and possibly the world. has already been declining on a much larger scale for over forty years, though fortunately this appears to be offset by an increase on the islands off Tierra del Fuego (G.S. Clark et al. in preparation.).

Thus it would appear that the numbers of southern seabirds as well as those breeding in Britain' have been fluctuating for longer and on a larger scale than there have been local overfishing and pollution problems.

Turkey maligned

Sir-Nechemia Meyers (Nature 321, 801; 1986) claims that visas had been denied by the Turkish Foreign Office to Israeli scientists seeking to take part in the Subcommission on Triassic Stratigraphy's field workshop (of whose organizing committee we are members) in Western Turkey between 14 and 23 July 1986. It seems, however, that Meyers was not particularly well-informed, for Dr Mordeckai Magaritz of the Weizmann Institute, to whom a visa had allegedly been denied, had left Israel before a visa could be issued to him. It was subsequently requested that his visa be sent to him in Milan, Italy, where he was attending the meeting on the Permian and Permo-Triassic boundary in western Tethys held in Brescia, Italy, between 4 and 12 July. The Turkish Foreign Office obliged him, thanks to the timely intervention of Dr Remzi Akkök, but Magaritz then claimed that it was too late for him, although it was certainly not too late to attend the meeting in Turkey. Two other Israeli scientists, Dr Baruch Derin and Dr Tuvia Weissbrod, not only obtained their visas, but also attended the Turkish field workshop. One thus wonders whether there really was any difficulty associated with the visa that prevented Magaritz from coming to Turkey.

Turkey is indeed cautious about issuing visas to foreigners for scientific work and visits. The reason for this is a long history of scientific plunder, first made famous by Heinrich Schliemann, mainly in such

fields as archaeology, epigraphy and mineralogy, to which this country has been subjected. This has harmed not only Turkey but also science itself. No particular nation has therefore been immune to close scrutiny in this regard by the Turkish Foreign Office and there is no reason why Israelis should be an exception.

African lakes

SIR-You published a year ago (Nature 315, 19; 1985) an article by Barel et al. entitled "Destruction of fisheries in African lakes".

Since then, a number of articles and reports have been published suggesting that Malawi plans to introduce the clupeid fish Stolothrissa tanganicae and Limnothrissa miodon (Kapenta or Ndagaa), which occur naturally in Lake Tanganyika, into Lake Malawi (formerly Lake

The government of Malawi therefore wishes to make it clear that it has no current plans, nor has it had any plans in the past, to introduce any exotic fish species into Lake Malawi.

Although the Malawi government wishes to maximize the sustainable fish yield from all its waters, it does not contemplate achieving this by resorting to the hasty introduction of exotics.

The views of the Malawi government on the subject of introducing clupeid planktivores into Lake Malawi are as follows:

- (1) There is at present insufficient knowledge of the chemistry, primary and secondary productivity, energy budget or trophic interactions of Lake Malawi to allow reliable predictions to be made about the outcome of any introduction.
- (2) Without such information, no introduction of any kind is justifiable.
- (3) If scientific studies suggest that the introduction of exotic clupeids could substantially increase the annual fish yield from Lake Malawi on a sustainable basis, without threatening the extinction of the lake's endemic fishes. Malawi would recommend the convening of multinational meetings, to include representatives of the three countries surrounding Lake Malawi and prominent fisheries scientists and biologists, to discuss and debate the issue before any action was taken.

Investigating the paranormal

SIR—In his Commentary on "Investigating the Paranormal" (Nature 320, 119: 1986) David Marks raises important issues about the problems of studying claims in areas where strong beliefs may be involved. With regard to parapsychology, however, his analysis (and that of many others quoted by him) appears to suffer from a lack of knowledge of the more process-oriented, systematic research that characterizes much present-day parapsychology. He claims that parapsychology is functioning without any theoretical bases. without any idea of what variables are relevant, in such a way that "every new investigator must start afresh, as though he or she is the first worker in the field". Yet much research in parapsychology explores the effect of experimental manipulations, as independent variables, upon measures of psi scoring as dependent variables. To appreciate this, one must be familiar with the details of original research reports. There are areas of research with partial replicability, that cannot yet be dismissed as "abortive leads"; current research does attempt to build upon them, as is evident from reading the introductory and discussion sections of research reports.

In his surveying of the value of the experimental research, Marks has relied upon two surveys of portions of that work, one by Akers' and one by Hyman². Both surveys conclude that parapsychological studies have many methodological flaws. I agree that much of the work has been flawed, but there has been considerable debate about the extent of such flaws. Marks, for instance, has ignored a fortypage response to Hyman's article by Honorton³ which appeared in the same journal issue. The debate over specifics continues, and doubtless will for some time

As Marks notes in his article, both John Beloff and I acknowledge that there has never been a perfect parapsychological experiment. What he does not explain, however, is that we argue that in areas studying extremely complex systems, as in the social sciences, it may be impossible to design, conduct and report a "perfect" study. In my article⁴, I list several groups of counterhypotheses to any given study which, by their very nature, are difficult if not impossible to falsify, such as experimenter fraud or improper description of procedure. Rather, I argued, it is better to evaluate parapsychology by focusing on groups of studies that appear to find consistent relationships between a measure of psychic functioning and some other variable; that such studies would provide more relevant evidence than studies merely finding simple deviations from baseline. I did not advocate examining "groups of studies which, although individually flawed reveal the undeniable presence of psi", nor did I advocate considering badly controlled experiments. As near as I can tell, Marks and I would agree that science progresses in its understanding by exploring functional relationships rather than merely documenting anomaly.

Lest I be misconstrued, certainly I agree that much of what has been done in parapsychology leaves something to be desired. Mistakes have been made, strong claims have been made by enthusiastic advocates, and theory construction has often been vague. Marks makes many good points about how advocates can be misled. But it is a mistake to assume that all who are willing to adopt the working hypothesis that there are new means of exchange between organism and environment are committed to a metaphysical belief system of some sort. If we are to improve our understanding of the phenomena explored by parapsychology, it will probably be through a more integrative approach, with more thorough evaluation of past work and better design of new research. An important component of such an integrative parapsychology would be the development of far more effective models for the strategies by which observers throughout the continuum of advocacy can be deceived by themselves and others about the nature of what they observe, perhaps along lines currently being developed by this writer's.

SIR—I should like to expose Marks's misleading simplification in the section of his paper on the paranormal headed "Coincidences".

Marks refers to Arthur Koestler and L.E. Rhine as publishing cases easily subsumed under the heading of coincidence. However, Koestler, for all his services to psychical research, did not investigate cases and neither, strictly speaking, did Rhine, who simply scanned for recurring features in reports that correspondents sent her. With the exception of one of Rhine's cases, those published by her and Koestler may indeed be interpreted as "simple coincidences". Other cases cannot be so readily explained.

The Society for Psychical Research gave attention to possibilities of coincidence from its earliest studies of apparitions in the late nineteenth century. This explanation may be appropriate for many ex-

periences that laymen attribute to a paranormal process. They sometimes claim that a dream or hallucination of a fairly ordinary type has a paranormal link with a contemporaneous or future event that corresponds in a general way with the dream or hallucination. However, the events concerned in other cases are not ordinary, recurring ones, but unique events. A man dies only once in his lifetime, and if another person at a distance becomes aware of unusual details in his manner of dying at the time it occurs, something more than coincidence must be in play.

Consider the case of Mrs Agnes Paquet, who had a vision of her brother falling overboard when his foot got caught in a tow-rope on a tugboat (almost) at the time the brother actually drowned in this manner. Her vision included details of her @ brother's clothing, such as that his pants legs were rolled up so that, as he went overboard, she could "see" their white lining. She was approximately 50 miles away when she had her vision of the accident to which it corresponded. She told her husband about her vision before learning of her brother's death by telegram. and he corroborated this. The event was unique and so was the perception⁶.

Students of paranormal phenomena, from Dr Johnson in the eighteenth century⁷ to Henri Bergson in the twentieth, have emphasized that when details of unique events are correctly communicated over long distances without the normal sensory channels we should not dismiss such experiences as coincidences.

Many cases, perhaps hundreds, like Mrs Paquet's have been published. Why should we not continue to study them?

Trouble on the farm

Sir—"Cheap and nasty trees" (leading article *Nature* **322**, 195; 1986) are the backbone of Scandinavian forestry. To suggest that they are not good enough for Britain is a striking example of how widespread is that British malaise responsible for so many of our current problems.

E. NICHOLL

Llangunville, Llanrothal, Monmouth, NP5 3QL, UK

What is the scientific literature?

Professional people have won a poor reputation for their skill at communicating with each other. The complaint may unfortunately be justified.

By what test are the scientific journals counted as literature? The bare minimum of an answer is that they are collectively referred to in this way by their contributors. Collectively, they also have the quality of permanence; they sit on library shelves for decades on end, and are referred to with reverence by those who contribute to later issues. So much is the bread and butter, or at least the bread and water, of scholarship; there are few complaints at the value of the accumulation of journals as the means by which the record of discovery may be reconstructed. But the same cannot be said of the value of the scientific literature as a means by which information is conveyed between people unable to communicate directly, by dialogue. Why should the general admiration of the way that discoveries roll off the laboratory benches coincide with a general belief that the scientific literature is impenetrable, often to its users?

There are some obvious excuses that do not deserve the dignity of being called explanations. Thus, some hold that the process of discovery inevitably splinters previously coherent fields of study, giving sub-fields an existence and a language of their own and creating barriers over which the practitioners no longer wish to jump. Others say that the content of science steadily becomes conceptually more difficult than can be handled by language as it is, which is a way of saying that the problem is not the fault of professional scientists but of other unspecified professionals. Still others protest that there would be no difficulty if only journals and their editors were more generous with the space they allow to the practitioners who are the creators of this growing volume of literature. All three defences are implausible.

That seems to be a legitimate inference from the opinions of regular readers of the journals, even journals such as this which aim to cater for readers with a variety of interests, both in particular but different fields of research and in more general matters. It is sobering how often those who kindly answer questionnaires about this weekly partial diet of science reply with the opinion that it must all be worthy, but that there are only a few parts of it that they could hope, and even wish, to understand. That there are conceptual difficulties that many people do not have the time to surmount is forgiveable. It is even proper that people working in some chosen field should choose to stay there, at least | for the time being. Why should everybody be required to be a generalist? But the sheer clumsiness of the scientific literature is a needless impediment not merely to wider understanding but even to the understanding of those at whom a specialized paper may be directed.

Although the common faults are not easily categorized (and people are forever inventing more), the general drift of error is generally understood even by the transgressors. There is, for example, a disinclination to believe that rules of grammar are particularly relevant to the understanding of scientific prose, whatever their significance in other connections. To judge from the literature as a whole, scientists care less for the accuracy with which the number of a pronoun agrees with that of its noun than they do for the numerical data they report, which is strange to say the least. It is also strange that people who fuss endlessly about the quality of reproduction of a diagram can so fecklessly scatter a word such as "only" in a sentence, forgetting that it belongs only where it most properly qualifies its antecedent.

To judge from much of what is published, most contributors must hope that inventiveness will see them (and others) through. Stringing long lists of words together was the strategem of the 1970s (as in "language-inventing-capability" or "DNA-binding-protein-sequence-homology"). The strategem serves no useful purpose because, until the string of words is so familiar within a sub-discipline that it can be represented simply by initials, it remains for the reader to unpackage the concatenation each time he comes across it. To how many is RFLP for "restrictionfragment-length-polymorphism" (or is it FLRP for "fragment-length-restrictionpolymorphism"?) a concept to hold in one's head as clearly as that of, say, "rabbit"? Even so some journals have now gone so far as to grade the length of the hyphens by which the words are separated in such a string, as if it were always possible to tell which pairs of consecutive words are the more closely related.

Meanwhile, new forms of inventiveness have already begun to appear. Ribose is a sugar which, when combined appropriately with a purine or pyrimidine phosphate, will make a nucleotide; everybody knows that. So why not coin the verb "to ribosylate"? There can be no objection. But what is the object of this ribosylation? ATP, or GTP, or something quite diffe-

rent? No problem. The statement suggests the solution. Why not "ATP-ribosylate", in whatever tense may be appropriate? The difficulty that unfamiliarity may often impede the understanding of even those who know what is intended will surely melt away in time, as the whole world takes the trouble to learn this special language?

The difficulty of the literature derives in part from the neglect of many common rules and the accompanying invention of others which are thought preferable. perhaps because they are better suited to the circumstances. But there are faults of a more structural character. The conventions of the research business, for example, require that authors' delight in what they have accomplished should be restricted to the use of conventional phrases, among which "for the first time" is unaccountably one. The result is that an author is prevented from giving an account of why his or her paper is important (which would help towards its understanding) but is allowed baldly to state that an observation has been made for "the first time in a closed vessel under water . . . ". Similarly, the convention that a person describing the results of a series of biochemical experiments should give such a full account of the details that a novice starting from scratch could repeat the work unaided is a pleasing concession to the need that work should be reproducible, but no substitute for an intelligent variation on some phrase such as "we followed so-and-so's method with this difference . . . ". Yet nobody seems to care that readers must each time unpackage each account of an experiment in the literature before they can properly understand its novelty.

Thus the underlying fault with the scientific literature is its intricacy, its requirement of readers that they should not merely read and understand, but read. pull to pieces and then put together again in ways they understand. Given the requirement, the process is plainly more prone to ambiguity than the ordinary person would think credible. And there is nothing in the demands of specialization. or in those made by editors on authors, to suggest that the characteristics of the scientific literature that give it a bad name are externally imposed. This, it seems, is what people want. But is not much of the rest of scholarship much the same? Of John Maddox

Bacterial-plant conjugation

A bizarre vegetal bestiality

from Conrad Lichtenstein

AGROBACTERIUM tumefaciens, a soil bacterium that transfers genetic material to plants, causes crown gall disease where the infected tissue divides rapidly to produce a tumour. Although much is now understood about this process, the mechanism by which the exchange of genetic information takes place remains mysterious. In a series of elegant experiments described on page 706 of this issue'. Stachel, Timmerman and Zambryski provide evidence that this mechanism is similar to that of bacterial conjugation. involving the unidirectional transfer of a single-stranded plasmid DNA sequence from bacterial to plant cells.

Virulent strains of Agrobacterium contain large (about 200 kilobase) tumourinducing (Ti) plasmids which have evolved an ingenious strategy for survival (see ref.2). When these strains infect wounded plants, a discrete portion of the Tiplasmid, the T-DNA, is transferred to and integrated within the nuclear genome of infected cells. The T-DNA encodes various genes which, by virtue of the possession of appropriate eukaryotic regulatory signals, are transcribed and translated in the plant tissue to produce novel enzymes. One enzyme (encoded by the tmr gene) directs the synthesis of a cytokinin (ribosylzeatin) and another two enzymes (encoded by tms1 and tms2. respectively) direct the synthesis of an auxin (indole acetic acid). It is the synthesis of these plant hormones at elevated levels that results in proliferation of plant cells to produce a callus or gall. Because the biochemical pathway for this synthesis is unusual, the normal plant mechanisms for regulation of phytohormone biosynthesis are evaded. Also encoded within the T-DNA are enzyme(s) that direct the synthesis of amino-acid derivatives collectively called opines; Ti-plasmids are classified according to the type of opine they specify, for example, nopaline or octopine. Once the plant is infected, the tumour (no longer requiring A. tumefaciens) continues to grow, releasing opines to the environment. These opines can be the sole carbon and nitrogen source for growth by agrobacteria that contain the relevant Ti-plasmid. Moreover, they act as molecular aphrodisiacs to derepress Ti-plasmid-encoded genes for conjugal transfer of the plasmid to avirulent agrobacteria in addition to derepressing the genes for opine catabolism.

How is the T-DNA element transferred to plant cells? Genetic analysis reveals three components required for this process: first, two genes, chvA and chvB, located on the agrobacterial chromosome, express products required for the initial binding or attachment of agrobacteria to plant cells'. Second, the T-DNA within the Ti-plasmid is flanked by cis-essential 25-base pair (bp) near-perfect direct repeats, the left and right borders (LB and RB, respectively). The T-DNA often terminates within (RB) or internal to (LB) the borders. Deletion of Ti-plasmid DNA encompassing RB (but not LB) prevents T-DNA transfer. Working on the nopaline Ti-plasmid. Wang et al.4 demon-

Schematic diagram of bacterial-plant conjugation.

strated that the 25-bp RB alone is sufficient to promote T-DNA transfer, but is only fully functional in one orientation (that normally found in the Ti-plasmid). This was the first clue that T-DNA transfer has a polarity, suggesting similarities to bacterial conjugation (see ref.5 for review). Third, the Ti-plasmid contains a large region (about 40 kilobases), the virulence (vir) region, encoding transacting functions required to promote T-DNA transfer; vir DNA itself is never integrated into the plane genome'. (These processes are shown in the figure.)

The realization that T-DNA itself encodes no trans-acting functions required for its own transfer has led to the exploitation of the Ti-plasmid as a vector to produce transgenic plants: a dominant drug-resistance marker plus other genes of interest replace the usual T-DNA genes. The transformed plant tissue can then be regenerated into a normal plant6.

Stachel et al.' performed a detailed genetic analysis of the vir region of an octopine Ti-plasmid. They constructed a transposon mutagen where the transposase is replaced by a promoterless lacZ gene encoding β -galactosidase. By supplying transposase in trans this transposon will insert randomly into a target DNA sequence. Insertion into an operon/ cistron will result in gene inactivation and also produce, in one orientation, a transcriptional/translational fusion to lacZ, so allowing analysis of gene regulation and direction of transcription by assaying for β -galactosidase activity. Using this tool, Stachel et al. show that the vir region contains six distinct operons, vir A, B, C, D, Eand G, involved in T-DNA transfer. Although virA and virG are transcribed constituitively, the other operons are expressed only when agrobacteria are cultured with metabolically active plant cells*.

Signal molecules present in Nicotiana tabacum (tobacco) exudates have been purified and identified as the phenolic compounds acetosyringone (AS) and α -hydroxy-acetosyringone (OH-AS)^{9,16}. These molecules, which fully induce vir expression, are produced by various plant cells at levels limiting for maximal vir expression. However, wounded plant tissue (the very tissue susceptible to infection) produces AS and OH-AS in greater amounts10. Thus, Agrobacterium has evolved to respond to compounds specifically representative of plants susceptible to transformation.

What other components are required for regulation of the vir regulon? The virA and virG loci are both needed for ASinduction of vir. Because this induction is highly attenuated and totally absent in virA and virG mutant cells, respectively, Stachel and Zambryski" speculate that virA encodes a membrane-associated sensory function that transmits the presence of the phenolic signal into the bacterium; this step leads to the activation of the virG protein which positively regulates vir transcription. Interestingly, virG expression is both constitutive and plant-inducible and produces two distinct differentially regulated transcripts: the constituitive transcript is shorter than the induced transcript and lacks sequences required for efficient translation. This feature is reminiscent of the PRE- and PRM-driven transcripts of the CI gene of bacteriophage lambda11

DNA sequence analysis also suggest that the virG locus encodes a 267-aminoacid protein with significant similarity to the ompR gene product of Escherichia coh^{v} . The ompR gene is needed for activation of expression of the outer membrane porins, encoded by ompC and ompF, and required for response to osmotic pressure. Quite how the virG protein activates transcription of the inducible vir loci is not yet clear. It could bind to operator sequences to allow RNA polymerase holoenzyme to initiate transcription. But virG appears to be expressed at a significant level, unusual for an activator, and maximal induction of the vir loci takes 12-18 hours. Alternatively the virG protein could replace the normal vegetative sigma factor in the holoenzyme complex specifically to transcribe the vir loci. Those loci, which are exclusively induced by AS, lack the -35 bp consensus sequence in the promoter yet have other hexanucleotide DNA sequences common around this region, which might function as cis-acting regulatory elements for vir induction13. Further mysteries remain with regard to vir regulation: although virG is absolutely required for expression of the other inducible loci, AS alone is partially able to induce virG transcription even when the virG protein is non-functional".

What is the mechanism of T-DNA transfer from agrobacteria to plant cells that results from vir activation? Initially it was thought that before transfer the T-DNA excises from the Ti-plasmid to form a double-stranded circular DNA molecule joined precisely within one border sequence repeat (by recombination between the two borders)14. However, this genetic evidence was circumstantial. In the report in this issue', Stachel et al. provide direct biochemical evidence that AS specifically induces the production of a linear, single-stranded, T-DNA molecule designated the T-strand; such strands are detected by Southern blot analysis of total DNA prepared from induced agrobacteria and are sensitive to different single-strand specific nucleases. These molecules correspond to the bottom strand of the Ti plasmid such that its 5' and 3' ends map to RB and LB, respectively, matching the genetic polarity of the border repeats. T-strand formation is probably associated with DNA synthesis as AS induction also yields molecular changes to

T-DNA sequences in the Ti plasmid — a strand-specific nick associated with the 25bp border repeats, and Ti-plasmids whose internal T-regions show partial singlestranded and/or triple-stranded character (presumably replicative intermediates). The border nicks probably direct sitespecific recombination to yield the doublestranded T-DNA circle molecule observed at low frequency after induction14.

This evidence suggests the following analogy to bacterial conjugation: after induction of the vir regulon by AS, a nick is made within the RB. New data (S.E. Stachel, personal communication) indicate that the function responsible for this nick (and T-strand formation) is encoded by the upstream cistron of virD. The virD gene is also necessary for the generation of T-DNA circle molecules¹⁸. Rolling-circle DNA replication is then initiated, and in conjunction with a helicase activity, extrudes the T-strand in the 5' to 3' direction. The LB nick signals termination of transfer and, when deleted, results in termination further along. The polar function of RB within the large Ti-plasmid indicates that in the wrong orientation transfer initiates in the other direction and is unlikely to traverse the entire Ti-plasmid to reach the T-DNA (analogous to an interrupted mating); in smaller plasmids the RB is fully functional in both orientations16. Can transfer initiate from the LB too? Probably, but recent evidence from octopine Ti plasmids indicates that RB is used more efficiently.

Many questions remain to be answered. How is the T-DNA transported from Agrobacterium to the plant nucleus? Where is the complementary strand to the T-strand made and what primes its synthesis? How does T-DNA integrate into the nuclear genome? Clearly, further exciting discoveries lie ahead in the understanding of the Agrobacterium-plant-cell interaction

Palaeoclimate

Permafrost and ice-wedge growth

from Peter Worsley

PERMAFROST, any natural material that contains a thermal state of 0°C or less for two or more years, underlies one fifth of the terrestrial surface of the Earth. Its formation is a direct function of climate; its boundaries are determined by a mean annual air temperature of 0 to -1°C. There are few precise data on permafrost establishment, so the study reported in this issue (Peyette, S. et al. Nature 322, 724; 1986), demonstrating that the removal of a forest cover, which normally promotes snow accumulation and hence protection from deep freezing, appears to be the key factor causing permafrost growth, is a significant confirmation of the sensitive environmental thresholds governing the onset of permafrost.

Permafrost is generally divided into three types - continuous, discontinuous or alpine - depending on its relative extent in the subsurface. Alpine permafrost is restricted to high mountains and plateaux outside the main polar-centric belt where altitudinal cooling replicates the severe subarctic. In the Northern Hemisphere the continuous/discontinuous permafrost areas form two concentric zones with boundaries frequently transverse to latitude because of permafrost sensibility to land-mass configuration. The transition between continuous and discontinuous zones corresponds roughly with a mean annual air temperature of -6 to -8° C.

Cracking of permafrost arises as a consequence of rapid cooling during winter in conjunction with ground temperatures in the −15 to −20°C range. Once initiated. the repeated annual cooling induces cracking of the frozen ground at the same location; successive events over several years, together with attendant infilling of the cracks with blown snow and hoar frost. leads to the slow growth of ice wedges. linear ground-ice bodies with V-shaped cross-profiles. Active growth of ice wedges has until recently been considered to be an exclusive property of continuous permafrost and, although ice wedges in discontinuous permafrost were known. climates associated with the arctic and I they were regarded as being dormant

Medium-sized ice wedges on an actively eroding coast in Banks Island, Canada (72°N, 130°W) in continuous permafrost (mean annual air temperature is about –15°C).

because of a climatic amelioration. Hence the wedges were thought to be relics from a former, more severe, climatic regime that could sustain continuous permafrost in the subsurface. The reappraisal of this view by Peyette et al., leading to the conclusion that active ice wedges do occur within discontinuous permafrost, was prompted by the study of T.D. Hamilton et al. (Arctic Alp. Res 15, 157; 1983) who, as a result of trench excavation during design of the trans-Alaskan pipeline. demonstrated ice-wedge growth in a mean annual temperature close to -3.5°C. The vegetation cover in the study of Hamilton et al. was similar to that which prevails in the interior subarctic boreal forest of Quebec.

Pevette et al. studied a site near Clearwater Lake in subarctic Quebec which has a mean annual air temperature of -5°C and extensive discontinuous permafrost. The association of ice wedges and peat allows radiocarbon isotope-dated, palaeoecological reconstructions of vegetation history, the latter being the key to their demonstration that ice-wedge initiation was a consequence of the removal of tree cover. The relationships between ice-wedge width and distance from the contemporary forest border uncovered by Peyette et al. are an elegant proof of the diachronous nature of ice-wedge initiation. Without the progressive retreat of the forest border no growth would have occurred, which emphasizes the need for caution in the deduction of climatic significance from such structures. But the host materials are highly organic and a low preservation potential is likely if the permafrost should degrade in the future.

Wedge-shaped sedimentary structures

in the geological record are usually considered to be casts arising from the melt of ice wedges. Such melting can be caused by regional climatic change or local factors such as thermal erosion of the ice by melt water during the summer. They are very valuable indicators of the former presence of permafrost and thus important aids to palaeoclimatic reconstruction. Climatic parameters derived from ice-wedge casts are usually based on the assumption that ice-wedge growth signifies continuous permafrost and therefore mean annual temperature of at least -6°C. No active

ice wedges have yet been found that originate in non-organic sediments within a zone of discontinuous permafrost. But in the light of the findings of Peyette et al. and Hamilton et al., a cautious re-assessment of the climatic values that control ice-wedge initiation and subsequent growth is necessary: factors such as rates and degree of cooling of the upper permafrost must now be considered.

Immune system

Complement-like cytotoxicity?

from Kenneth B.M. Reid

BOTH cytotoxic T cells and natural killer cells have cytoplasmic granules containing the protein perforin, which appears to have an analogous function to that of serum complement component C9 in the lysis of target cells12. Activation and regulation of the complement system is quite well understood but little is known about the system that controls perforin activity. Efficient and controlled lysis of target cells by the complement system involves six serine proteases3. It might be expected that natural killer and cytotoxic T cells contain a complex complement-like regulatory system and recent studies at the protein and complementary DNA levels, one of which appears on page 740 of this issue', indicate that this is the case as there appear to be at least two serine proteases involved in cytotoxic T-cell activity.

Pasternack et al. find that a serine protease is involved in the antigen-specific lysis of target cells by mouse cytotoxic T cells (and certain helper T cells). The principal protease identified is composed of two, probably identical, disulphide-linked subunits of approximate relative molecular mass (M_i) 32,000 (32K). Inhibition of this protease by diisopropyl-phosphorofluoridate and its limited trypsin-like activity indicate that it belongs to the serine protease family. The enzyme appears to be associated with the membranes of the perforin-containing cytoplasmic granules and its release is specifically triggered by the interaction of cytotoxic T cells with target cells.

Studies at the cDNA level by the isolation of clones specific for cytotoxic T cells predict protein sequences for three molecules having the characteristic features of the classical serine proteases, that is, a chain of $M_r \approx 25 \text{K}$ containing the highly conserved residues, such as those at the active catalytic site, His, Asp and Ser. Brunet et al. reported the isolation by subtractive hybridization of a mouse cDNA clone (CTLA-1) specific for cytotoxic T

cells but not helper T cells or B cells. The sequence predicts a leader peptide of up to 20 amino acids followed by a sequence of 227 residues resembling a serine protease beginning with the characteristic Ile-Ile-Gly-Gly amino-terminal sequence.

An identical cDNA sequence has been identified by Lobe et al." who first found two genes encoding serine proteases that appeared to be specifically expressed in activated cytotoxic T cells, just before the cytotoxic reaction. But on screening cDNA libraries using the genomic probes, coding sequences for only one of the proposed proteases (CCP1) could be isolated. In another study the cDNA encoding a serine protease-like sequence different to that seen for CTLA-1/CCP1 clones, was isolated from a mouse cytotoxic T-cell cDNA library' using an RNA hybridization competition procedure. The sequence of this clone predicted an aminoterminal sequence of 14 amino acids (which seems likely to be part of an activation peptide rather than a leader sequence) followed by 232 amino acids of serine protease-like sequence. The molecule identified (HF) was found in all cytotoxic T-cell clones, nude mice spleen cells and rat natural killer cells examined but not in control tissues and cell lines.

The derived amino-acid sequences for the two serine protease-like molecules CTLA-1/CCP1 (refs 5,6) and HF (ref. 7), show 40 and 35 per cent homology with rat mast cell protease II, an intracellular serine protease found in the granules of atypical mast cells8. Human factor D (refs 9,10), the first enzyme involved in the activation of the alternative pathway of complement, shows 36 per cent homology with the rat mast cell protease" and appears to be the most closely related of the complement serine proteases to the mouse cytotoxic T-cell-specific proteases. The presence of an Asp residue in the position determining the substrate specificity of the HF protease indicates that, like

factor D and the other complement enzymes, it would have a preference for lysyl or arginyl bonds. This is consistent with the observation of Pasternak et al.4 that the protease they describe has a limited trypsin-like activity.

The presence of Ala in the equivalent position in the other cytotoxic T-cellspecific protease, CTLA-1/CCP1, makes this likely to be more similar to the rat mast cell protease II in its activity. The CTLA1/CCP1 protease further resembles the mast cell protease in that it has Phe, rather than the highly conserved Cvs seen in all other serine proteases, at the position four residues on the amino-terminal side of the serine at the active site, and this could affect the substrate binding pocket. Also, the presence of an uneven number of Cys residues in the derived amino-acid sequence for the CTLA-1 and CCP1 sequences (and perhaps HF) implies that the Cys at position 74 has a free sulphydryl group, or is linked by a disulphide bond to another chain, as it has no homologous counterpart in all other known serine protease sequences. It is possible that the disulphide bond in the dimer observed by Pasternack et al.4 involves this Cvs residue. This would certainly be a novel observation and could be a feature of cytotoxic T-cell-specific serine proteases.

Thus it is possible that the CTLA-1/ CCP1 and HF clones encode two of several distinct serine proteases in a lytic pathway common to natural killer and cytotoxic T cells. Cytotoxic T cells perhaps follow a classical antigen-mediated pathway whereas natural killer cells may use an alternative pathway not involving the T-cell receptor, with both pathways culminating in a common lytic process. If there is close homology between the lytic processes of these two cell types and that of the serum complement system then proteins homologous with the complement components C3, C4 and C5 may be found acting as substrates for these recently identified serine proteases, thus allowing generation of complex proteases similar to C4b2a3b and C3bBb3b that are involved in the generation of C5b in the serum complement system.

Membrane biophysics

Surface conduction of protons

from M.J. Selwyn

In an elegant series of experiments on phospholipid monolayers, Prats, Teissié and Tocanne, on page 756 of this issue, report that protons move much more rapidly in a thin layer (less than 0.5 nm thick) at the interface between the lipid and aqueous phases than through the thickness of the aqueous phase (a few millimetres). This model system provides experimental evidence for a reactionfacilitating function of membranes and is particularly interesting in relation to chemiosmotic coupling by protons. The result also has implications for the study of reactions at non-biological interfaces, such as catalysis by immobilized enzymes.

The Langmuir trough technique, used since 1917 for measuring the surface pressure and the cross-sectional area of the constituent molecules of monolayers is that they can measure this parameter for any phospholipid without the perturbations caused by an added probe group.

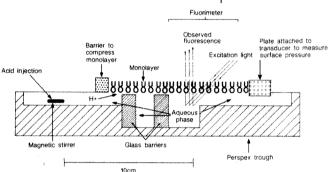

They find that reporter-group signals change more rapidly than the pH of the aqueous phase and that there is both a pH gradient along the surface of the membrane and a steep pH gradient from the interface through a thin layer (measured by the linked fluorescein, estimated to be 1.0 ± 0.5 nm into the aqueous phase) to the bulk aqueous phase. Thus, fast diffusion along the interface and slower diffusion into the bulk aqueous phase compete for interfacial protons. Fast diffusion disappears if the lipids are not sufficiently tightly packed in the monolaver. which suggests some structural requirement. But increasing the ionic strength with NaCl or thiocvanate does not alter

> the rates of diffusion². which indicates that 'structured' water is not involved. In contrast, increasing the concentration of K'phosphate in the buffer increases trapping of the protons by the aqueous phase much that conduction along the interface

> cannot be detected' Although it is now generally agreed that electron transfer and synthesis oxidative and photosynthetic phosphorylations are coupled by the flow of protons. quantitative some data do not

with P. Mitchell's original concept' that the protons equilibrate with the bulk aqueous phases and others exclude the alternative hypothesis of R.J.P. Williams in which the protons are confined to the membrane. Since then there have been a plethora^{6,7} of hypotheses suggesting semilocalized proton coupling in which the resistance to transfer of protons to the bulk phase is neither infinite (as in Williams hypothesis) nor zero (as in Mitchell's).

The main points of contention are whether there are structural barriers to proton flow to and from the bulk aqueous phases; whether there are specific channels between the proton-linked enzymes: and the extent of localization of the protons, ranging from the whole surface of each vesicle membrane down to units comprised of single sets of the proton-

Diagrammatic longitudinal section of a Langmuir trough modified for injection of acid and measurement of fluorescence changes at and near the surface (from refs 1-3). Fluorescence is detected both in the monolayer and in the aqueous phase just below it. Thus, depending on whether the fluorescein pH indicator is attached to the lipids in the monolayer or free in solution the fluorimeter responds to the pH at the interface or to the pH of the bulk aqueous phase, respectively. Controls are provided by pH measurements at the same position in the bulk aqueous phase without the monolayer or the glass barriers. The shorter time-constant for pH change when the monolayer is present demonstrates rapid conduction of protons at the interface.

spread on a water surface, is adapted by Prats et al. so that they can inject acid at one end of the trough and, further along, measure changes in the aqueous pH and signals from chemical groups attached to the monolayer (reporter groups) which have a readily measurable property that responds to changes in the local environment (see figure). In previous experiments^{2,3} they found the pH close to the lipid-water interface by changes in the fluorescence of fluorescein that is covalently linked to phosphatidylethanolamine. In their new work1 they use americium electrodes to measure changes in the surface potential of the lipid monolayer and thus the state of ionization of the lipid headgroups. This ionization depends on the pH precisely at the interface and one advantage for Prats et al. linked enzymes. Calculations suggest that even in the aqueous phase the movement of protons should be so rapid that without special barriers the protons have rapid access to the whole surface of the membrane and to the bulk aqueous phases. But the results of Prats et al. indicate that proton movement away from a phospholipid membrane is not rapid, even in the absence of special barriers, and so steady-state fluxes of protons between sources and sinks on the membrane surfaces and to the internal and external aqueous phases should be considered.

On this basis the bulk-phase pH and membrane potential are not equal to the local values either for the reductionoxidation enzymes or for the ATPase, but there is no definite distinction between localized and delocalized coupling. An analogy can be made with a spring or fountain where a collector placed close to the source can collect water at a higher potential energy than that in the surrounding pool. Unless diffusion of protons across the surface of the membrane is infinitely fast then there will be a progressive tendency for proton-linked enzymes to be more tightly coupled and more isolated from the bulk phases the closer they are on the membrane surface. With this type of situation, depending on conditions, the system may tend either towards localized or delocalized behaviour, and indeed Beard and Dilley8 recently showed such a change by storing thylakoids in high rather than low ionicstrength medium.

Adam and Delbrück" proposed that intracellular membranes enhance reactions rates by constraining diffusion to two dimensions on the surface of the membrane. This hypothesis has been criticized10, partly on the grounds that a great reduction in diffusion rate at the surface offsets much of the advantage. But the rapid movement of protons at the membrane surface may affect the rate of many reactions and maintain uniformity of cytoplasmic pH. Although monolayer experiments are a very simple model, they should also stimulate investigation of other ions and non-biological surfaces.

Astronomy

Neutron stars in Nanjing

from Virginia Trimble

NEUTRON stars form in supernova explosions, manifest themselves as radio pulsars or X-ray binaries, and fade away as their rotation slows, their magnetic fields decay away and their energy supplies are used up. This basic framework has been accepted for nearly 15 years, so that one might wonder whether there was anything left for a conference on the origin and evolution of neutron stars* to discuss.

But several fundamental questions (and a host of minor ones) remain. Are there other ways of making neutron stars? And, perhaps most important, when and how do they acquire, then lose, the strong dipole magnetic fields and rapid rotation that permit pulsar emission and provide signatures of neutron-star presence in X-ray sources? Unsurprisingly some possible answers are emerging from studies of two very rare classes of pulsars — those with rotation periods less than 10 ms and those with compact (white dwarf or second neutron star) binary companions. The classes overlap in that two of the three known millisecond pulsars are among the seven known binary ones. Two papers by Joseph H. Taylor and colleagues on pages 712 and 714 of this issue^{1,2} report the most recent additions to each group. More can be expected, for they probably make up about 10 per cent of all galactic pulsars, according to Taylor (Princeton University) and Ramesh Narayan (University of Arizona), and are currently under-represented in catalogues only because their intrinsic faintness and rapid pulsation makes detection difficult.

What are the binary and millisecond pulsars telling us? First, they provide the firmest evidence so far for neutron-star formation not from the collapse of the core of a massive star, but rather from collapse of a roughly solar mass white dwarf driven above the Chandrasekhar (maximum stable) mass by accretion from a companion³.

This mechanism, originally invoked to account for young-looking neutron stars with 1012 Gauss magnetic fields among old, low-mass X-ray binaries, seems to be the only way to explain the combination of young neutron star (1011 Gauss surface field) and old system (wide, circular orbit) that characterizes the binary pulsar 0820+ 02 (ref. 4). A recent detection of the companion' strengthens the explanation. The other star is a hot white dwarf, which must have ceased transferring material to its companion about 107 years ago, the elapsed time being just right for the white

*IAU Symposium No. 125 was held in Nanjing, China, 26–30 May 1986.

dwarf to cool to its present temperature and for the neutron star to have reached is present field and rotation period (0.865 s).

Initially strong fields and rapid rotation are expected simply from conservation of magnetic flux and angular momentum as stellar cores collapse to neutron stars. Statistics of pulsar periods, period changes, and associations with supernova remnants tell us, however, that only about 20 per cent are born with the largest possible values of both field and angular velocity. Stanford E. Woosley (University of California, Santa Cruz) suggested that some neutron stars might be born as slow rotators from progenitor stars larger than 10 solar masses, because core convection during carbon and silicon burning could transport angular momentum outward. Lower masses without such convection would give rise to rapid rotators.

The alternative of low initial surface field must also sometimes occur, for instance in LMC X-4, whose massive companion requires the neutron star to be young. Given the 69-ms rotation period, the accretion that fuels observed X-ray emission can only occur with a surface field less than 3×10^{10} Gauss, according to Nicholas E. White (Darmstadt). If, when

100 years ago

The August Perseids

THE shower of Perseids has been a fairly conspicuous one this year notwithstanding the somewhat unfavourable circumstances attending the display. On the nights of August 9, 10, and 11 the nearly-full moon was visible during the greater part of the time available for observation, and robbed the phenomenon of its chief prominence during the evening hours. Those, however, who continued to watch the heavens until after the moon set on the early morning of the 11th must have been rewarded by a tolerably rich exhibition of meteors. The number observable by one person fell little short of 100 per hour, and this rate compared with similar observations in past years proves the late display to have fully maintained its decided character. Numerically this shower of Perseids cannot be placed in the same category as the brilliant meteoric storms of November 13, 1866, and November 27, 1872 and 1885, but it must be remembered that the August shower is one which returns annually, and apparently without much variation in its leading features.

From Nature 34, 372; 19 August 1886.

or how such initially low fields grow to typical values of 10¹² Gauss is not certain, though mechanisms have been suggested.

In any case, pulsars then live on their rotational (and, perhaps, magnetic) energy until dropping below detectability at periods of a few seconds and affective fields of 1011 Gauss, preventing the study of later phases. One catch is that only the dipole part of the field perpendicular to the rotation axis is measured, so that one could not rule out the field aligning or evolving to higher multipoles rather than decaying in the 10°-10' years over which pulsars fade away. The binary pulsars have opened a new window for observation of senile neutron stars. As the companion evolves and expands, gas transferred to the neutron star spins it back up to an equilibrium rotation period, depending somewhat on orbit parameters and field strength, but typically a few milliseconds. Later, when the companion itself has become compact or unbound and ceased to interfere, we see a recycled pulsar with rapid rotation and low field.

One might expect the magnetic field strength to continue to drop. Apparently it does not'. All three millisecond pulsars have fields very close to 5×10^8 Gauss. according to Taylor. This includes the binary 0655+64, whose white dwarf companion' has been cooling for several billion years since it stopped spinning up the neutron star. Corroborative evidence for stalling of field decay at 108-109 Gauss comes from models for quasi-periodic oscillations in old (low mass) X-ray binaries*, although so many different kinds of correlations of the frequencies of these oscillations with X-ray intensity and colour temperature have now been seen that the connection with any one model has become very tenuous according to Guenther Hasinger (Max Plank Institute, Munich).

Apparently, then, we can add to the basic framework mentioned above an alternative mechanism (accretion-driven white dwarf collapse) and alternative evolutionary histories for rotation and surface magnetic field more complex than simple monotonic decay with time.

Other neat, new things that were reported at Nanjing included a report from Andrew Lyne (Jodrell Bank) of the largest glitch ever, $\Delta P/P = 4 \times 10^{-6}$, which occurred in January or February 1986 in PSR 0355+534 (P=0.156 s). The recovery has also been unprecendentedly rapid ($\vec{P} = -52 \times 10^{-24} \,\text{s}^{-1}$). One might or might not want to tie this up with the suggestion by Charles Alcock (MIT) that post-glitch behaviour is a possible test to distinguish true neutron stars from interlopers made of strange quark matter. Claire Flanagan (SAAO) described a new glitch in the Vela pulsar almost as large $(\Delta P/P = 10^{-6}).$

Jiehao Huang (Nanjing University)

advocated dividing pulsars into two roughly equally numerous groups that emit at polar caps and at their speed-oflight cylinders respectively; and Tan Lu (Nanjing University) had statistical evidence that the fading of pulsar radio luminosities may not be monotonic with time.

Patrizia Caraveo and Giovanni Bignami (Milan) have added another late-1985 EXOSAT point to the curve of period as a function of time for the 60 s pulsation of Geminga. The object is still slowing down and now shows two harmonics as well as the fundamental. Caraveo and Bignami have not, however, been able to get additional optical images to test the possibility of large proper motion. Zhenru Wang (Nanjing University) suggested several new possible identifications between Chinese guest stars and young neutron stars and supernova remnants (including Geminga!).

W. David Arnett (Chicago) has found a new instability following core collapse in massive stars that may advect enough energy and momentum outward to cause envelope ejection and a supernova explosion. The most recent round of neutronstar cooling calculations requires pion condensation, strange quark matter or some other non-standard physics to prevent the Vela pular from emitting more thermal X rays than the observed upper limit, according to Ken'ichi Nomoto (Tokyo) and Sachiko Tsuruta (Montana State University). These are just a few of the facts presented at Nanjing, which it is hoped will form the raw materials for a new synthesis

Immunology

The ins and outs of antigen processing and presentation

from Ronald N. Germain

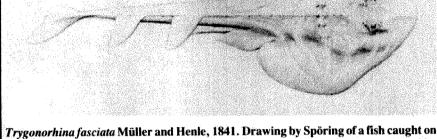

THE striking differences in antigen reactivity shown by T and B lymphocyte subpopulations has been the primary research interest of many members of a whole generation of immunologists. The expectation that elucidation of the structure of the T-cell receptor would, by itself, reveal the how and why of the differences has proved false1. Therefore, increasing attention has been paid to understanding the form of antigen actually involved in the T-cell recognition process. The studies of Townsend and his collaborators²⁻⁴, culminating in a recent paper', provide a major advance in our understanding of the form of antigen seen by T cells and provide an intellectually and physiologically satisfying explanation for several poorly understood immunological phenomena.

Although very similar gene segments and DNA rearrangement events are involved in generating the receptors used by T and B cells, the functional specificity of these two cell types differs markedly. B cells express surface membrane versions of serum immunoglobin molecules that directly bind soluble antigens of diverse chemical composition. In contrast, T cells use a recently characterized heterodimer to co-recognize particular combinations of protein antigen and class I or class II major histocompatibility complex (MHC)encoded molecules on the surface membrane of other cells⁷.

As early as 1958, Gell and Benacerrafs pointed out that antibodies tend to be specific for native protein molecules, whereas cell-mediated (now known to be T-cell-mediated) responses such as delaved-type hypersensitivity are stimulated by determinants preserved after protein denaturation. Pioneering work by Ziegler and Unanue' demonstrated that antigen presentation to class II MHC-restricted T cells is an active time-dependent process involving an acidified intracellular compartment whose function is sensitive to drugs such as chloroquine. These results suggested that the antigen seen by T cells is not intact, but rather degraded or denatured intracellularly before exposure on the surface of the antigen-presenting cells10. Shimonkevitz et al.11 direct evidence in support of this hypothesis by showing that proteins enzymatically degraded in vitro could be presented by metabolically inactive cells bearing the proper class II molecules.

Thus, physiological priming of class III restricted T cells to degraded forms of antigen accounts for the presence of secondary T-cell responses to protein antigens denatured in vitro and for the success many have had using protein fragments or synthetic peptides as stimuli for T cells originally generated by immunization with intact proteins. Both indirect and direct methods have now revealed that at

Pictures from the *Endeavour* voyage of 1768

Trygonorhina fasciata Müller and Henle, 1841. Drawing by Sporing of a fish caught on 29 April 1770 at Sting Ray Bay (later Botany Bay), Australia. T. fasciata was based by Müller and Henle partly on this drawing, but also on another specimen in alcohol at the Paris museum. From Catalogue of the Natural History Drawings commissioned by Joseph Banks on the Endeavour Voyage 1768–1771 Part 3: Zoology, recently published by the Bulletin of the British Museum (Natural History). (Historical series vol. 13; London, 1986.) This catalogue lists all the drawings of animals from James Cook's voyage on the Endeavour that were made by artists employed by Joseph Banks. Most of the drawings were kept in Banks' home until his death in 1820 and then transferred to the Museum. This catalogue attempts to record comprehensively the surviving animal drawings from the voyage of the Endeavour, and examines and discusses the history of the drawings as well as providing notes on the artists, none of whom survived the voyage.

least some of these minimal antigens interact physically with class II molecules in the absence of the T-cell receptor, providing an understandable picture of how simultaneous recognition of the two is achieved.

This view of antigen presentation to class II-restricted T cells diverges markedly from the present view of antigen recognition by class I-restricted T lymphocytes, especially cytotoxic T lymphocytes (CTL). These cells seem specific for integral cell-membrane molecules such as viral envelope glycoproteins, allogeneic MHC molecules, or minor histocompatibility antigens that have been assumed (without any experimental evidence) to be uncharacterized membrane proteins. Immunologists presumed that these intact membrane proteins interacted directly with class I MHC molecules on the cell surface. However, such a marked difference between class I and class II antigen interaction became less and less likely as accumulating data showed striking similarities between the relationship of both class I and class II molecular structures to T-cell recognition¹³, and the use of the same Vand V_n gene segments by the receptors of class I- and class II-restricted T cells.

Experiments

The experiments of Townsend et al. 5 now reveal that these differences are more imagined than real, and that similar (though not necessarily identical) forms of antigen participate in recognition by all MHC-restricted T cells. The new findings

come from work on the specificity of both human and murine CTL generated by immunization with the influenza virus. Early studies' demonstrated many CTL clones that recognized specificities shared by distinct serotypes of this virus. The viral protein accounting for this cross-reactivity was, unexpectedly, the nucleo-protein and not the membrane-expressed haemagglutinin molecule. Confirmation of these results was obtained using L cells co-transfected with the proper class I gene and the nucleoprotein gene. These cells were recognized appropriately by the cross-reactive CTL clones'.

Given that interaction of CTL receptors with target cells occurs at the outer surface of the cell membrane, how can a molecule that does not appear on the membrane serve as a target antigen? This conundrum was partially solved by the demonstration that transfectants expressing truncated forms of the nucleoprotein molecule could serve as adequate CTL targets4. Finally, the experiments described in their most recent paper? show that, just as synthetic peptides could be used to stimulate class II-restricted T cells, target cells exposed in vitro to short synthetic peptides corresponding to certain regions of the nucleoprotein molecule could be recognized by nucleoprotein-specific CTL. The active peptides, as would be expected, correspond to regions of nucleoprotein sequence of the immunizing strain of virus that differ from the sequence of nucleoprotein of a strain of virus incapable of sensitizing cells for recognition by these particular CTL clones. Thus, it appeared unnecessary for the intact nucleoprotein mysteriously to reach the cell surface. Instead, some fragmented or degraded form probably serves as the antigen after travelling to the membrane by a mechanism independent of the normal intracellular sorting process acting on the intact nucleoprotein.

Similarities

Thus, we now have a satisfying similarity in the general nature of antigen recognized by both class I- and class IIrestricted T cells. The new data on CTL recognition also provide an explanation for the repeated failure of investigators to generate antibodies to minor histocompatibility antigens. Rather than constituting a family of intrinsic cell-membrane molecules, these antigens are more likely to represent processed fragments of cytoplasmic or nuclear proteins that normally never reach the membrane in an intact state, just as with influenza nucleoprotein. Even if antibodies were raised in response to the very small amount of such fragments that probably are present on the cell surface, they are not likely to be detected in binding or cytotoxcity assays.

The studies on influenza-specific CTL support the emerging view that antigen processing is not a specialized function of a small subset of class II-bearing, bone marrow-derived cells, but rather the reflection of a more fundamental set of intracellular activitites occurring in virtually all cells. An early hint that this might be the case came from experiments showing that fibroblasts made to express class II antigens by DNA-mediated gene transfer could also present various protein antigens to T cells, and that this function is susceptible to the same inhibitors that interfere with processing by haemato-poietic-presenting cells¹³. The demonstration by Townsend et al.5 that class Irestricted T cells are specific for antigen fragments suggests that most, if not all, cells have some capacity for antigen processing, because class I molecules are widely distributed on various somatic cell types, and CTL recognize virally infected or minor histocompatibility antigenbearing cells of diverse tissue origin.

Is the same intracellular pathway used for processing those antigens taken up from the external environment of the cell and those synthesized endogenously? Do both classes of MHC molecules interact with or present the same processed antigens? Recently published work by Morrison et al. "suggests the answer to both of these questions may be 'no'. These investigators find that influenza haemagglutinin sythesized endogenously can not be recognized by class II-restricted, haemagglutinin-specific T-cell clones, but provide an adequate target for class I-restricted cells. Conversely, the class I-restricted

clones ignore class II-bearing cells that had taken up haemagglutinin protein from the culture medium, which are excellent stimulators of class II-restricted lymphocytes. Furthermore, only the class IIdependent antigen presentation is sensitive to the drug chloroquine. Thus, there may be at least two distinct mechanisms for the production of immunogenic protein fragments, and there may be different pathways of intracellular transport for class I and class II molecules that determine the nature of the antigens with which they are recognized.

Model

possible

plasmic

A speculative scheme of antigen processing and presentation to T cells that takes into account these new data, the demonstration of binding between antigenic peptides and MHC molecules¹², and the recent intriguing report by Cresswell¹⁵ on the presence of class II molecules within the endocytic pathway, is given in the figure.

For exogenous protein antigens, the universally distributed endosomal recycling pathway¹⁶ is considered to have the central role, accounting for the ability of diverse cells to carry out antigen processing. Intact proteins enter the cell by either (fortuitous) binding to molecules engaged in receptor-mediated endocytosis, or as a result of pinocytosis. As the endosomes acidify during their intracellular passage,

this change itself, or the activation of acidpH-dependent, cathepsin-like proteases leads to the denaturation and-or fragmentation of the original protein molecules. A subset of the resultant peptides, perhaps already associated with class II MHC products, is transported to the cell surface in vesicles bringing molecules such as discharged transferrin receptors back to the membrane. The remaining peptides may go to the lysosomal compartment for complete degradation.

For endogenous proteins, processing may occur in a region of the transitional Golgi specialized for dealing with improperly folded proteins synthesized by the cell. Denatured or fragmented molecules in this compartment may escape sorting into secondary lysosomes, and be transported to the cell membrane along or together with class I molecules.

In both cases, selection of peptides for surface expression presumably depends on structural features that either enhance binding to MHC molecules or other potential carrier proteins cycling to the cell membrane, or that reduce the potential for transport to lysosomes. The α helical state that is hypothesized to be an important feature of immunogenic segments of a protein molecule may be critical in this regard^{17 18}. Once it is on the cell membrane, the antigen fragment would be available for recognition by the T.cell in conjunction with the appropriate MHC molecule.

Why did such complex schemes of antigen processing and presentation evolve? It has been suggested that antigen denaturation or fragmentation is necessary to create molecules with increased lipophilicity, thereby stabilizing interaction with the plasma membrane and increasing the effective local concentration of antigen in the environment of the MHC molecules. In addition, if direct binding of antigen to MHC molecules is essential for T-cell recognition, then proteins that in their native state are much larger than MHC molecules may need to be fragmentated to be effective immunogens.

What is particularly apparent in this emerging story is that phenomena considered to be primarily of immunological interest turn out to involve processes of substantial general importance to cell biology. Elucidation of the intracellular events involved in antigen processing will have broad import for our understanding of the traffic patterns followed by proteins within cells. The contributions of Townsend et al. remove a major conceptual stumbling block to research in this area and progress should now occur at an accelerating rate. It is also clear that this new picture of antigen recognition by CTL has important implications for the rational design of synthetic vaccines.

Finally, one should not forget the original question — what does the T cell see? With a solution of the crystal structure of HLA close at hand, the capacity to identify the minimal antigenic peptide recognized by a specific T cell together with this class I MHC n lecule may provide the means to create a physical picture of the antigen-MHC at lecular complex bound by the T-cell receptor.

illustration shows a schematic view of the several R (He pathways followed by antigen and MHC-encoded (H) B molecules in an antigen-presenting cell. E Endogenous antigens, such as viral ٥ Ď GOLGglycoproteins or nuc-ENDOSOME leoprotein, are syn-♦ ٥ LOW pH thesized in the endo-reticulum LYSOSOME and transported to the Golgi where they B are shown in an Ð intact and partially 0 degraded from. The peptide representing the immunogen then reaches the cell surface either 1) already G. ⅆⅎ associated with class (H-2, HLA-R CLASS II MHC (la) **EXOGENOUS ANTIGEN ENDOGENOUS ANTIGEN** A,B,C) molecules also exiting from ■ - PRESENTED R - PRESENTED 4 the Golgi in exoo - DEGRADED → - DEGRADED CLASS I MHC (H-2,HLA) cvtic vesicles (Path-

way A, top left), or 2) alone (Pathway C, bottom left), following which the peptide associates with class I molecules already on the cell membrane. For exogenous antigens presented in the context of class II molecules, intact antigen enters the cell by means of endocytic vesicles. As these acidify and partial proteolysis occurs, the immunogenic peptides are associated either 1) with class II molecules recycling from the cell surface in the same endosomes (Pathway B, upper right); 2) with newly synthesized class II molecules from the Golgi (Pathway E, centre); or 3) with class II molecules on the membrane, following transport of the peptide to the cell surface in exocytic vesicles (Pathway D, lower right). In all cases, other peptides are shown here as being transported directly into lysosomes for complete degradation, never reaching the membranes, and hence are unavailable to serve as immunogens.

Radionuclide deposition from the Chernobyl cloud

SIR—The accident at the Chernobyl nuclear power station in the Soviet Union created a cloud of radioactivity that affected a surprisingly large area of Europe. This letter concentrates on the main passage of this cloud over the United Kingdom and presents some results of preliminary investigations into the collected data on radioactivity levels in the air, in rain water, on grass and in milk, and attempts to link the time variations of these levels to meteorological conditions. In particular, we report that high levels measured on grass are linked to heavy rainfalls associated with thunderstorms embedded in the radioactive cloud.

The accident is believed to have begun at 01:23 local time on Saturday 26 April (20:23 GMT on Friday 25 April) and to have ended on the following Wednesday or Thursday. By the Monday, countries throughout Europe had been alerted and possible trajectories of the plume were being estimated, based on standard meteorological data. In many cases, analyses and forecasts from numerical weather prediction models were being used. Trajectories calculated at the Meteorological Office early in the week indicated a possible risk to the United Kingdom, and this possibility was strengthened when, on Wednesday, enhanced radiation levels were reported in northern Italy, indicating a first arrival in the United Kingdom on Friday 2 May.

Since then, more thorough analyses of the cloud movement have been carried out at the Meteorological Office and at many other centres throughout Europe, and Fig. 1 shows the most probable path of the cloud that affected the United Kingdom. This part of the cloud appeared to leave Chernobyl at ~12.00 GMT on 26 April, ~16 h after the start of the accident. The cloud moved rather slowly within the lower layers of the atmosphere towards the Baltic, and then on the Monday a finger moved more quickly southwestwards over Poland, Czechoslovakia, Austria and the Alpine area, as a result of a growing zone of high pressure running across the Low Countries from south-west to north-west and a depression over the Adriatic. When this high moved away on Thursday towards the north-west, the cloud turned forthwestwards over France towards the United Kingdom.

The requency of environmental montoring at a number of stations was inerce ed, and the National Radiological Protection Board acted as a focal point for collating and interpreting these data¹². Reports of elevated radiation levels in southern England were received before midday on Friday 2 May, and by late evening the cloud had reached the north

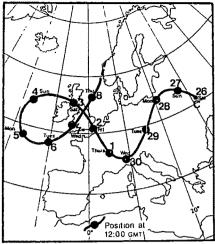

Fig. 1 Estimated path of the Chernobyl radioactive cloud which ultimately crossed the British Isles (26 April to 8 May 1986).

of England. The peak levels of γemitting radionuclides in the cloud were in the ranges shown in Table 1, and air concentrations in this range were observed later in Scotland and other parts of the British Isles, during the period 3-5 May. From this monitoring data and the data collected at the Meteorological Office we can derive a picture of the passage of the cloud, and Fig. 2a,b shows its position at 03:00 and 18:00 GMT on Saturday, 3 May. The cloud had entered Britain across the Kent-Sussex coast at ~05:00 GMT on the Friday morning, and moved northwards, until by the end of the day most of Britain was covered except for Cornwall, Devon, the western extremities of Wales and north-west Scotland. Generally, Friday was dry 'nd sunny, the air being of continental origin, although a few showers were experienced in the Solway and Clyde areas late in the day.

On Saturday some old thunderstorms moving up from France were revitalized as colder air aloft was advected over the warm continental air, owing to a rapidly deepening low-pressure area to the southwest of the country. These storms first affected the south-east in the early hours, and then moved over East Anglia and out into the North Sea. New storms developed rapidly in the morning over central England. These moved slowly northwards to Cumbria and south-west Scotland, feeding off the warm air in the lowest kilo-

metre of the atmosphere containing radionuclides from Chernobyl, and causing the cloud to shrink in area. By early Sunday morning the cloud was affecting Scotland alone, and by 09:00 GMT it had been swept westwards from the Outer Hebrides, only to return, at much lower concentrations, the following Wednesday and Thursday, having been swept right around the large low to the west. There is some evidence for a separate small part of the cloud having affected the United Kingdom on Sunday, when it seems the winds turned towards the south-east for a couple of hours, allowing a remnant from France to move northwards along the extreme east coast onto the far north of Scotland, where local rain gave high levels of radioactivity.

Radionuclides washed out by the rain produced elevated y-ray backgrounds of up to 0.6 uSv h⁻¹ (about three times the normal level) in areas where it rained heavily, and this rain-out effect could be observed directly by measuring deposition densities on grass, as has been reported'. The effect was reflected more directly in concentrations in rain water (Table 1), which varied from 10 to 1×10^4 Bq I⁻¹ for ¹³¹I. The highest levels were those reported from Scotland², which were very close to the derived emergency reference level (DERL) for ¹³⁴I in drinking water³. The DERLs are based on an effective dose equivalent of 5 mSv or an organ dose of 50 mSv, which ever is the more restrictive, corresponding to the annual dose limits recommended by the International Commission on Radiological Protection for exposure of the public over a few years. The levels in rain water were followed by elevated levels in foodstuffs such as vegetables and cows' milk, but levels of "I in these foodstuffs did not exceed DERLs in any part of the country. The incorporation of radionuclides into animal tissues has been monitored by the Ministry of Agriculture, Fisheries and Food, which has issued data on meat, milk, vegetables and other foodstuffs5.

It is possible to use food monitoring data to infer deposition in areas of the country that could not be directly monitored, and match this with data on rainfall from the Meteorological Office. For example, subsequent monitoring of

Table 1 Ranges of peak air and rain-water concentrations of radionuclides observed in the British Isles during 2–5 May 1986

Radionuclide	Air concentrations (Bq m ⁻³)	Rain-water concentrations (Bq l ⁻¹)
131 <u>T</u>	1–10	10-10,000
¹³² Te- ¹³² I	1–10	10-10,000

How many reactor accidents will there be?

SIR—The designers of nuclear reactors claim that the chance of a reactor accident should be less than one in 10° per reactor year. The US Rasmussen report and the German safety study found that there is a fifty-fifty chance that such accidents could occur every 23,000 and 10,000 reactor-years respectively. Two or three serious accidents suggest the standard has not been met in practice, and that the method of 'technical risk assessment' used to calculate such probabilities must be replaced by risk assessments which use data from operating experience.

At the end of 1985, according to the IAEA data file', there were 374 reactors in operation in the world with a total operating experience of 3,831 years. We assume that until the end of May 1986, the cumulative operating experience had been 4,000 years. There had been two major accidents - Three Mile Island and Chernobyl — during this operational period.

We do not count the Windscale of 1957 because it was a military reactor. We think that the reactor designers would claim that the safety systems of early reactors were not as good as the present ones. The British reactor designers were under pressure at that time. Military commitment to build several plutonium producing reactors came at a time when the civilian nuclear programme was emerging. The nuclear industry was expanding so quickly that there was an acute shortage of experienced scientists and engineers.

We assume that the accidents are a Poisson process with intensity r. The probability of finding two accidents in an interval of length T = 4,000 reactor-years is then Poisson distributed:

$$P(2, rT) = r^2 T^2 e^{-rT}/2$$
 (1)

If we want this to be a probability density, we have to normalize it. The normalization being:

$$N(T) = \int_{-\infty}^{\infty} dr P(2, rT) = 1/T$$
 (2)

The density is then

$$P_r = r^2 T^3 e^{-rT}/2 (3)$$

The numerical value of P_r is not a probability. However, we can think of P.dr as the element of probability — for example, the probability that r lies between r_1 (0.0004) and r, (0.006) is obtained by integrating equation (3) between r_1 and r_2 and is found to be 0.21. This indicates that the probability that one significant accident will occur between 1,667 and 2,500 reactor years is 21%.

Another way of dealing with this density is to take into consideration that the

probability of the occurrence of at least one accident in a Poisson process of intensity r in a time interval t is

$$P(1,rt) = 1 - e^{-n} \tag{4}$$

Since r is unknown, we have to integrate equation (4) overall r with the 'empirical' density P as a weighting factor, that is:

$$P(1,t) = \int_{0}^{\infty} dr (1 - e^{-rt}) r^{2} T^{3} e^{-rt}/2$$

= 1 - (1 + t/T)⁻³ (5)

Equation (5) gives the probability of having at least one accident during the next t years. The probability that a reactor accident could happen during the next decade ($t = 374 \text{ reactors} \times 10 \text{ years} =$ 3.740 reactor-years) is 86%.

There is no circularity in the arguments used above. There must be some input data in any model. Our input is two accidents in 4,000 reactor years. Of course, we know that two accidents are not 'representative'. With 374 reactors in operation. we would naively expect one accident every 5.4 years. But our model assigns a 70% probability that one accident could happen in the next 5.4 years, not a certainty. Similarly the probability of having one accident every two decades is more than 95%.

It is true that events with high probability need not necessarily materialize. But how can we reconcile these findings with the claims of the reactor designers that the chance of a reactor accident should be less than 10 " per reactor-year? The reactor designers calculate such probabilities with

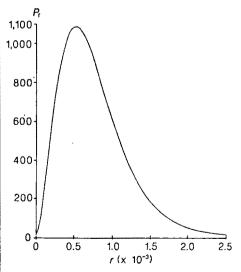

Fig. 1 P_c gives the likelihood of a significant accident given the total operating experience of 4,000 reactor-years and two significant accidents. The number of significant accidents per reactor year is measured by r. The probability that this number lies between r_1 and r_2 accidents per reactor year is given by the area under the curve between r_1 and r_2 , that is, by integrating equation (1) between r_i and r_{ij} .

the help of a decision tree. The likelihood of the failure of a reactor component or safety system is assessed and its consequences on other components or subsystems are estimated. These results in their turn are inputs for a chain of calculations leading to probabilistic risk assessment used by the reactor designers. Since the number of vulnerable components is rather high, this procedure cannot be rigorous. Our view is that this method should be replaced by risk assessment using the observed data.

¹³¹I in ruminant thyroids after nuclear releases

SIR—The substantial yield of 131 I from nuclear fission, its energetic β and γ emission and its concentration in the thyroid gland have led to the recognition of this nuclide as a significant nuclear hazard¹⁻³. In the late 1950s the Medical Research Council funded a study of 131 I accumulation in the thyroid glands of sheep from fallout arising from nuclear weapons tests. This study was in progress during the accident at Windscale in October 1957 and during the Northern Hemisphere weapons testing of October-December 1958 in which 29 (17 Soviet and 12 American) weapons were detonated. British weapons at that time were detonated in the Southern Hemisphere, having little effect on fallout in the United Kingdom².

It was therefore of interest to measure 131 I accumulation in sheep thyroid glands following pasture contamination with fallout from the Chernobyl reactor, to obtain a comparison with the earlier measurements. Thyroid glands were collected from fatstock from 20 May to 17 June. At this time sheep were at pasture and hence directly ingesting any nuclides on the grass. Because of the late spring, fat cattle were generally not at pasture at the time of maximum contamination, on 2 May'.

Figure 1 shows thyroid ¹³¹I radioactivity from sheep grazing in Scotland during the autumn of 1958' and in East Anglia during

the spring of 1986. It can be seen that thyroid radioactivity following the Chernobyl accident was marginally higher than that resulting from the nuclear weapons testing during the autmun of 1958. By contrast, the highest sheep thyroid "I measured in the maximum deposition area near Windscale 31 days after the reactor accident was 7.4×10⁴ Bq g⁻¹, 300 times higher than the radioactivity measured after Chernobyl. In the sheep thyroid glands recently measured, the radioactivity had a half-life on storage of 8.05 days, showing that ¹³¹I alone was present. Comparison of radioactivities on different dates of collection showed a biological half-life of about 6 days.

Cattle thyroid glands are less useful than those of sheep for monitoring fallout, because of the widespread practice of feeding beef cattle indoors on stored fodder for much of the year. Thyroid 131 I in stall-fed sheep following a period of radioactive fallout from nuclear weapons testing by the United States showed only 0.7% of the radioactivity in grazing sheep4; a limited number of human thyroids also showed ~ 1% of the radioactivity of sheep4. Five cattle thyroids collected recently in East Anglia showed a mean of 0.97 ± 0.13 Bq g⁻¹, compared with $99\pm5 \,\mathrm{Bg}\,\mathrm{g}^{-1}$ for sheep killed the same day. One other cow, however, had 61.7 Bq g 131 I, which must have resulted from grazing on contaminated pasture.

Data already published showed human thyroid radioactivities after Chernobyl of 2-33 Bq, the highest concentration being ~7 Bq g⁻¹, in a child, while adults showed a maximum radioactivity of 1.7 Bq g⁻¹. Sheep thyroid radioactivity on the same date measured 243 \pm 48 Bq g⁻¹ (n=15), with a range of 39-703 Bq g

¹³¹I from a reactor accident is capable of contaminating pasture for a considerable distance downwind. Most human inges-

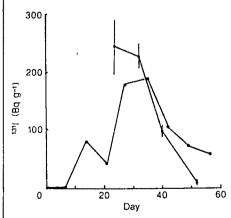

Fig. 1 Sheep thyroid radioactivity following the reactor accident at Chernobyl (1) and the nuclear weapons testing of the autumn of 1958 (•). Day 0 has been taken as the day of the Chernobyl accident (26 April 1986), or the peak of nuclear weapons testing (3 November 1958). ¹³I activity is given in Bq g⁻¹ wet weight of gland (± standard error of mean).

tion of tal derived from fallout comes through milk, as the mammary gland effectively concentrates dietary iodine into milk". To minimize the human ingestion of ¹⁴I, a reasonable precaution would be to feed dairy cattle stored fodder while pastures are measurably contaminated.

I thank Mr Martin Collins for collection of the thyroid glands and the University Pathology Department for the use of their γ-counter.

Fault striations slip from sight?

SIR—Communication of ideas begins with agreement on the meaning of terms. Unfortunately, in discussions on mesofaults and their surface textures, terms are endowed with different meanings with alarming ease thus giving rise to considerable confusion. A glaring example is the term 'slickenside'.

Linear structures on fault planes (grooves or fibrous grains) represent the orientation of the relative displacement between adjacent fault blocks. Recently many techniques have been developed to determine from slip orientation data the attitude and relative magnitudes of the principal stresses responsible for the deformation. Such data are of paramount importance in the study of neotectonics relating recent plate motions to deformation within continents. The problem is that some authors12 use slickenside to refer to planar structures whereas others² use it to describe a lineation.

Etymologically slickenside smooth plane, which is how it was first defined in 1822. Surely this should remain as the agreed meaning. The associated linear structures are best termed striations; qualifying words, such as fibre and scratch, are adequate to distinguish accretionary crystal growths from abrasion structures4.

Star on the make?

Colin Patterson

The Nemesis Affair: A Story of the Death of Dinosaurs and the Ways of Science. By David M. Raup. Norton: 1986. Pp. 220. \$15.95, £12.

"I HAVE never seen Francis Crick in a modest mood" is one way to start a book; "This is the story of an emerging scientific theory about the extinction of dinosaurs and other prehistoric life forms" is another. With the first sentence of *The Double Helix* we know just where we are—the academician is out of school, the bag is open and the cat is flying, together with whatever else was in there. The opening of *The Nemesis Affair* does not set the scene so plainly. Is the academician in or out of school, and if in, what class are we with?

Of course it is unfair to compare David Raup's book with Watson's, but Raup is used to the ways of science and knows they are not paved with fairness. It is not often that a leading professional tells the tale while still close to the events — Raup calls it "a view from the trenches" - and the Watson/Raup comparison does bring out aspects of the ways of science. For one thing, the pace is killing today: there was a gap of 15 years between the events Watson wrote of and his book, whereas Raup hits the streets only two years after the birth of Nemesis, the name given in Nature of 19 April 1984 to a possible companion star to the Sun, producing periodic comet showers and mass extinc-

Nemesis was born as one of several possible causes for a possible series of events. In February 1984 (Proceedings of the National Academy of Sciences, 81, 801-805), Raup and Jack Sepkoski published a statistical analysis of Sepkoski's data on the first and last appearance of each marine family in the fossil record. They concluded that extinction is non-random, with a 26 Myr periodicity; one of their eight bestfitting mass extinctions is at the Cretaceous/Tertiary boundary, hot property since 1980 because of the iridium spike which may imply extraterrestrial impact. Six weeks after the Raup and Sepkoski paper in PNAS came the 19th April Nature containing an editorial by John Maddox, a "News and Views" piece by Tony Hallam, and a block of five papers, all bearing on extraterrestrial causes of periodic mass extinction. (Turning back to Nature in 1953, the Watson and Crick paper didn't merit mention in "News and Views", which then read rather like the Court Circular.) Maddox's editorial commented (Raup calls it "mild wrist slapping") on the practice of distributing preprints, which in this case resulted in the possibility of the *Nature* papers appearing *before* the Raup and Sepkoski data they purported to explain. John Maddox saw this as "a kind of nonsense", but at least it is nonsense with a limit. The pace can get no hotter once the hound and hare coincide.

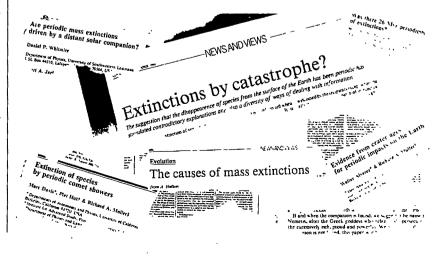

Since 1984, it is hard to pick up a journal in the fields of geology and evolutionary biology which doesn't contain a paper, review or meeting report touching on mass extinctions. DNA was slower to get up steam, but once it got going it was unstoppable, and we all know what has been achieved. Can we expect a similar profoundly important research programme from Nemesis et al? I think not, and Raup gives no real sign that he thinks otherwise. He ends his book with some comments on the pecking order from "hard" to "soft" science, placing molecular biology at the hard end and palaeontology (his own field) at the soft. We can see now that Watson and Crick's achievement was to begin to move parts of biology from the historical (soft) towards the physical (hard) end of the spectrum to put some determinism among the contingency. Periodicity in mass extinctions, and extraterrestrial explanations for it, might seem to promise the same for parts of palaeontology. But, so far, the controversies over periodicity and the less general question of extraterrestrial impact as the cause behind particular extinctions exemplify the field of sociology (which Raup puts right at the bottom of the pecking order) as much as hard science. Recalling Raup's "view from the trenches", those involved seem first instinctively to have either volunteered for the neocatastrophist revolutionary force

rallied to the flag of Lyellian uniformitarianism, and then started looking around for ammunition. (The latest skirmish in *Nature* was "Matters Arising" in May this year (321, 533-536).)

Raup has some level-headed comment on the prevalence of prejudice and preconception in his chapter on "Belief Systems in Science", but ultimately the Raup and Sepkoski periodicity thesis (and so the possibility of Nemesis) rests on the quality of Sepkoski's taxonomic data. That is where I believe the thesis is weakest, but the attack will necessarily be slow and piecemeal. The Double Helix was a success story, whereas Raup's book may turn out to be (as he acknowledges) just the happier half of a chronicle of failure. If so, he may find a benefit in avoiding "saganization", the word he coins for the (unmerited) fall in professional esteem that accompanies the rise in visibility of any scientist taken up by the

Like The Double Helix, Raup's book can be read at a sitting. What gripped the reader in Watson's story was the personalities, the emotions, the indiscretions. Perhaps because he is still so close to the events and to the people, Raup has left all that out; his colleagues or opponents are characterised as no more than "brilliant", "prominent" or "hardworking". No one will take offence at the book, but the lack of emotion or indiscretion means that the narrative and the writing have to do a lot of work. On the whole, they stand up to the strain; the pace of the narrative picks up in the second half of the book once the scene has been set, and the writing is good popularization, though occasionally slipping a bit too far down market. The first words of "what is known as the Upper Eocene" or "what are called the Middle and Upper Jurassic" are no sop to anyone, and the sentence that Raup and I (unfairly) begin with does not set the true tone of the book.

When they stayed away from Paris

Robert Fox

Science in the Provinces: Scientific Communities and Provincial Leadership in France, 1860-1930. By Mary Jo Nye, *University of California Press*, 1986. Pp. 328. \$39.95, £33.95.

OVER the past decade, the community and institutions of French science in the nineteenth and early twentieth centuries have been subjected to an unprecedented onslaught by historians. Oddly, the trail has been blazed by scholars working in Britain and North America, and it is they above all who have fashioned the developing consensus to which Mary Jo Nye's book makes a notable contribution. In the new orthodoxy, two points have emerged strongly. The first is that in the half century or so before the First World War the majority of French savants abandoned their traditional preoccupation with abstraction and pure knowledge and became increasingly concerned, even besotted, with the applications of science. The second is that the scientific life of the provinces deserves to be treated quite as seriously as that of the capital and that it is quite misleading (though understandably convenient) to equate an assessment of Parisian science with that of French science as a whole.

Both of these points are developed to good effect in Science in the Provinces. The book is structured around a series of studies of the science faculties of Nancy. Grenoble, Toulouse, Lyons and Bordeaux, and it uses those studies to display the faculties as seats of scientific vitality and institutional innovation, with local industrial, agricultural and commercial interests often serving as a source of problems and a spur to action. Strikingly, Nye's faculties all lie in a crescent sweeping from the Gironde, through the Midi and up into Lorraine. Here, it seems the provincial tradition in science developed with special vigour: certainly, it would be hard to think of professors in the faculties of the centre or the north-west of France at Clermont-Ferrand, Poitiers or Rennes, for example - who would bear comparison with the undisputed "stars" who sustain Nye's case for each of her five

By digressing liberally on the work of individuals, rather than attempting a comprehensive prosopography. Nye allows the content of the science she treats to come to the foreground, where it belongs. Not all the science has stood the test of time, to be sure: René Blondlot's false discovery of a new radiation — N-rays — in 1903 is a case in point. But by the time

Victor Grignard (of Lyons and then Nancy) and Paul Sabatier (of Toulouse) shared the Nobel prize for chemistry in 1912, the provincial faculties of science had to be taken seriously, the more so as certain professors (including Grignard and Sabatier) ostentatiously refused the call to a Parisian chair. Their resistance was understandable: good facilities, local adulation and a sense of contributing to the regional economy were the rewards on offer and, for about 20 years from 1900, they sufficed to reduce the flow of talent to the capital. In the longer run, however, what seems to have been the natural order of things reasserted itself. By the 1930s, the provincial faculties had become once again the poor relations of a cripplingly impoverished university system, and even Grignard had lost his old assertiveness and hope that the imbalance between Paris

and the provinces might be removed.

Nye's discussion of Grignard adds poignancy to the story of a valiant but doomed campaign for diversity. It is a story well worth telling and with some bearing on present educational debates not only in France but also in Britain. It suggests, at least to a reader of gloomy disposition, that although centres of excellence can be fashioned on the margins of the traditional academic world, they are instrinsically fragile creations condemned to a thorny path and, in all probability, an ephemeral existence.

Robert Fox is British Academy Reader in the Humanities at the University of Lancaster, Lancaster LAI 4YG. From September, he will be Director of the Centre de Recherche en Histoire des Sciences et de l'Industrie at the Cité des Sciences et de l'Industrie, 75930 Paris Cedex 19, France.

Stones in the service of society

D.V. Ager

The Stones of Britain: Landscapes and Monuments, Quarries and Cathedrals. By Richard Muir. *Michael Joseph: 1968. Pp.288. £15.95.*

When we were in the United States and our daughter was only one year old, she greatly impressed the locals by referring to the erratic blocks of the glaciated Mid-West as "rocks" rather than "stones". That came of growing up in a geological family. Geologists do not study "stones" unless they be of the "precious" or "semi-precious" variety. The only other exception is building "stones", which are the main subject of Richard Muir's book.

Muir is a geographer and tells us right at the beginning that he is not writing about geology because "geology is a technical Skara Brae in the Orkneys. I have a theory

subject". So this is a book for the architect and the aesthete rather than the scientist. It is a book about man in Britain using the rocks beneath his feet, first for implements, then for monuments and finally for buildings.

The first part deals with "stone" in the landscape. This Muir divides into three: "Hard Rock Landscapes", which means chiefly the granites of Cornwall and the Ordovician volcanics of the Lake District; "Sandstone Scenery", which curiously includes the brick-making clay-pits; and "Landscapes of Limestone", which includes the chalk but hardly the flints which that lithology contains.

Flints come into their own in the next part of the book, on the use of stone by prehistoric communities. Here are accounts of stone tools (which, it is worth recalling, served man for nearly 99 per cent of his history and of which there is a particularly good record in Britain), cave dwellings (somewhat inappropriately) and then the first stone huts, starting with Skara Brae in the Orkneys. I have a theory

that the oldest buildings in Europe — in the Orkneys and in Malta – are still there simply because of the ease with which the local stone could be worked so that it was not worth the trouble of pulling the huts down again to build more up-to-date residences. Muir then moves on to burial chambers and stone monuments. He makes some rather doubtful remarks about Stonehenge but does not mention the unlikely theory (albeit sanctified in the Geological Museum) that the "blue stones" were brought from Wales by ice rather than by human muscle.

The third and most interesting part of the book deals with what the author calls "The Rise and Fall of Building Stone" in the great mediaeval cathedrals and castles. The biggest problem was the cost of transport before the coming of canals and railways, when the movement of heavy materials was largely restricted to natural waterways. The local stone was mostly Jurassic limestone or Devonian sandstone, though other local rocks were obviously used when convenient. Muir describes quarrying methods, and the mason's art in relation to changing architectural styles, and relates economic and social history to the remarkable phenomenon of great stone buildings which only ended (as I see it) with gunpowder, Ann Boleyn and the Reformation.

There is much less in the book about domestic architecture, the triumph of which was surely the cottages and walls of the Cotswolds with the "sunlight" in their local Middle Jurassic limestones, and even less on post-mediaeval building in stone. The use of Permian Magnesian Limestone in the Houses of Parliament is mentioned, though not the disastrous effects of the acid London atmosphere in turning them into Epsom Salts!

Muir talks disparagingly of brick (also apparently a form of "stone"), but does not, in my view, say enough about the uppermost Jurassic Portland Stone which Wren used to rebuild church and state in London after the great fire of 1666 and which then spread throughout southern Britain as the pale face of bureaucracy. Thus, characteristically, it is used in Swansea for the Guildhall, whilst the prison is built more prosaically of the local Pennant Sandstone. Banks, on the other hand, seem to depend on the Aberdeen granites to give them a proper air of dependability, while Cornish granites provide our hardwearing kerb-stones.

For its intended audience this is a fascinating book, well-written and easy to read. Personally, I would have liked to have had also a simpler guide, little more than: "Salisbury Cathedral — Chilmark Stone" and then where Chilmark is and the geological age of its building stone.

Derek Ager is Research Professor in the Department of Geology, University College of Swansea, Swansea, SA2 8PP, UK.

Fascinating family

Frances C. James

Blackbirds of the Americas. By Gordon Orians. *University of Washington Press:* 1985. Pp.163. \$24.95, £18.

When American ornithologists use the term "blackbird", they mean a member of the subfamily Icterinae, a group confined to the Western Hemisphere. Among the 94 species are not only the familiar red-winged blackbird, the brown-headed cowbird and the common grackle, whose immense roosts are a nuisance to farmers, but also many colourful species of New World orioles and meadowlarks, and the tropical oropendolas and caciques. The lineage is as diverse in social behaviour and breeding biology as it is in physical appearance and distribution.

Gordon Orians' fascination with blackbirds has taken him from Canada to Argentina, from marshes to deserts, from savannas to tropical forests. In this attractive volume, he introduces American blackbirds to the layman, the birdwatcher who has mastered the field guide and wants to learn more. His informal writing style, in combination with the many striking drawings by Tony Angell, makes the book seem friendly, even though it is densely packed with information. And the comparative approach, a la David Lack, leads to new perspectives on the subject matter.

In an attempt to touch more generally on what evolutionary biologists do. Orians describes his own experiments and those of others. He discusses applications of optimal foraging theory and kin selection theory to interpretations of behavioural data, and confesses that the work was not designed to test these constructs but merely to use them to organize information. Here both the strengths and weaknesses of a controversial area of biology are revealed. The sceptical layman may well decide that biologists are still a long way from the goal of understanding mechanisms of adaptation

The book is dressy, rich in detail and vet easy to read. References and appendices are included for the reader who wants to go further. Orians has fully achieved his objectives, perhaps even more than he intended.

Frances C. James is a Professor with Department of Biological Science, The Florida State University, Tallahassee, Florida 32306 U.S.A.

For the future

Lynton K. Caldwell

World Resources 1986: An Assessment of the Resource Base that Supports the Global Economy. World Resources Institute and International Institute for Environment and Development. Basic Books/Harper & Row:1986. Pp.353. Hbk \$32.95, £22.95; pbk \$16.95, £11.95.

This reference source is the first volume of a projected annual series. Aspects of ten resource-environment topics are reviewed, with data tables for each of them and also for selected materials, minerals and basic economic indicators. Subsequent volumes will cover other aspects of the subject and a new one, on biogeochemical cycles, is planned for 1987.

Among the topics covered are population; human settlements; food and agriculture; forests and rangelands; wild-life and habitat; energy; freshwater; oceans and coasts; atmosphere and climate; and policies and institutions. The editors acknowledge the difficulty of organizing a volume in which all the material is interrelated, but while some division by topic was unavoidable and artificial the reader is assisted by a detailed table of contents, an index and frequent cross-referencing.

A further difficulty in compiling a book such as this is the frequent inadequacy of

the information available. The editors found "gaping holes in basic knowledge", and the prospects for closing these gaps are often diminished by lack of reliable indicative criteria and of comparability of the data. One of the main objectives of the World Resources series is to help remedy these deficiencies, and to provide assessments of the global resource base that can be relied upon in the formulation of national and international policies for resources and environment.

World Resources 1986 is an impressive compilation, well-designed for ready reference. Some minor textual errors are inevitable in a production of this kind, out I found no misleading errors of substance. It is not, however, the only source of information on world resources and environment. Since 1984 the Worldwatch Institute, under the direction of Lester R. Brown, has published an annual State of the World report - but although the two publications deal with many of the same issues they are complementary rather than competitive. Both are predicated on the proposition that the world environment is rapidly deteriorating under human mismanagment, but can be saved if timely action is taken. Both avoid the "gloom and doom" approach to the predicament of mankind. In 1984 the World Resources Institute sponsored The Global Possible Conference, principal papers from which were published in 1985 by Yale University Press. Similarly, the Worldwatch volume is advocacy for an

ecologically sustainable society which its editors and authors believe to be possible.

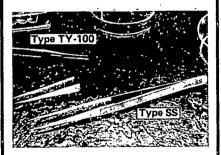

Having emphasized the virtues of these reports. I should point out what they do not offer. They do not provide a comprehensive survey of scholarly and scientific research on the topics covered (nor should this be expected). And, although they are policy-orientated. I believe that few social scientists would regard their views on such matters as adequate or indeed as realistic.

World Resources 1986 is largely a straightforward and factual account. I have no quarrel with the conclusions reached in the treatment of policies and institutions, but the report as a whole does not address the question of the human will to achieve the "global possible". Neither. unfortunately, have social and behavioural scientists seriously addressed this question, although some have begun to ask it. The "global probable" would have more to do with values, assumptions, ideologies and behavioural patterns than with ecosystems or energy production. An assessment of human prospects for realizing the possible could be very useful in developing strategies for a sustainable

Energy for life

Owen T.G. Jones

The Vital Force: A Study of Bioenergetics. By Franklin M. Harold. W.H. Freeman: 1986. Pp.577. Hbk \$37.95.£19.95.

BIOENERGETICS attempts to explain how cells generate useful energy and how this conserved energy is used in the enormous range of activities that can be defined as work. As these activities include the capacity to respond to changes in the environment, to move, to grow and to reproduce. it is apparent that a comprehensive account of bioenergetics could encompass much of biochemistry and cell biology. Dr Franklin Harold has accepted the challenge in The Vital Force. He not only covers well the expected topics of oxidative phosphorylation, photophosphorylation, ion transport, active transport processes and muscle contraction, but also includes the motility of bacterial and animal cells and the involvement of ion fluxes in the transduction of signals from the cell membrane to the cytosol and the nucleus.

It is, of course, ambitious of one author to range over topics which are so extensive and which are developing rapidly, but his attention to the bioenergetic aspects of these complex events permits him to disentangle common properties of apparently disparate processes. The significance of protein phosphorylation in regulating cellular activities and the everincreasing evidence of the importance of changes in the concentration of intracellular Ca²⁺ and other ions in cell division and differentiation support Harold's wide-ranging coverage.

The book opens with a comprehensible and simplified account of the thermodynamics necessary to understand problems of bioenergetics. The author adopts the view that the major disputes of the chemiosmotic wars are now settled and that energy conservation is by mechanisms closely related to those proposed by Peter Mitchell. He does, however, give an account of the background to these disputes - such as whether energy coupling arose from protons extruded into the bulk phase or from protons localised within the anhydrous phase of the membrane - and also explains why there have been such a range of values for the ratio of protons translocated during electron flow to ATP produced. In following his explanations. the reader will gain an understanding of the thermodynamics of ion movement and ATP synthesis and why it is important. From this clear account, the reader will also learn what a proton-motive Q cycle is. why it is necessary for a satisfactory formulation of the chemiosmotic hypothesis, and the relative merits of redox loops

and conformational pumps as mechanisms to transport protons.

The author is particularly familiar with the energetic problems of microorganisms and he writes on these with authority. Bacteria can face alarming problems of maintaining osmotic pressure and cytoplasmic pH near neutrality whilst growing at a pH2 or pH11 or in salt concentrations around 5M. Their strategies for coping with life at these extremes are not fully understood, but Harold does show how much information of very general significance can come from the study of relatively obscure organisms. Halobacteria. for example, have the simplest of proton pumps and the determination of its structure has been a great stimulus to thought. One minor criticism is that Harold's description of the reaction centre of photosynthetic bacteria does not include an account of its crystal structure which has so elegantly confirmed the arrangement of pigments and electron transport carriers which he describes. These had been predicted by bioenergeticists from their more usual techniques of measurement of flash-induced spectroscopic changes during the generation of light-driven transmembrane electric field. Such structural studies on complex protein assemblies are at last starting to answer some of the important questions about fundamental mechanisms in energy conservation.

The Vital Force is a substantial volume. in size and content. It will be a useful reference book for the specialist and will provide a good initiation for the more general reader. In the area of accepted bioenergetics its coverage is comprehensive and authoritative. On the topics Harold is now claiming for bioenergetics - the cytoskeleton, the generation of intracellular signals and morphogenesis he brings to our attention much important and exciting work. The measurement of the movement of Ca²⁻ ions is likely to provide as much employment for biochemists and cell biologists in the future as has the measurement of proton movements in the past.

Owen T.G. Jones is Professor of Biochemistry, Medical School, University of Bristol, Bristol BS8 1TD, UK.

Gene regulation by proteins acting nearby and at a distance

Mark Ptashne

Department of Biochemistry and Molecular Biology, Harvard University, 7 Divinity Avenue, Cambridge, Massachusetts 02138, USA

Transcription of genes can be controlled by regulatory proteins that bind to sites on the DNA either nearby or at a considerable distance. Recent experiments suggest a unified view of these apparently disparate types of gene regulation.

THERE are many examples in prokaryotes and eukaryotes of the following phenomenon: a protein bound at a specific DNA site influences the transcription of a gene hundreds or even thousands of base pairs away. For example, in eukaryotes, proteins bound at a site called an enhancer can turn on transcription of a distant gene. Regulatory proteins thus influence the activity of another protein (RNA polymerase) at a distance—how is this possible? Those who would tentatively throw all such examples into one basket and search for a common mechanism (and I am one) divide into distinct camps: the twisters; sliders, oozers and loopers.

My purpose is to review selectively recent experiments that support the loopers and to varying degrees weigh against the first three camps. The discussion unfolds within the context of our firm understanding of how one class of regulators, exemplified by the λ -phage repressor, recognizes DNA and turns transcription on or off. In that case proteins bind to adjacent sites on helical DNA and regulate transcription by touching one another, a matter I explain more fully below. The loopers imagine that proteins bound at widely separated sites act in the same way, contacting each other, with the intervening DNA looping or bending to allow the protein-protein interaction. According to this idea, it is the interaction between DNA-bound proteins, not the looping per se, that regulates gene expression.

In the course of this article I shall first consider the evidence for looping and then define and argue against the contrasting mechanisms. I shall consider experiments involving both gene transcription and site-specific recombination. The latter phenomenon (at certain stages) requires that proteins acting at separated sites on the same DNA molecule communicate with each other, and mechanisms for how that interaction occurs have been critically tested.

The case for looping

The first indication of looping came from studies of gene regulation in Escherichia coli. Adhya and co-workers^{1,2} showed that two operators separated by some 90 base pairs are required for efficient repression of the gal operon and suggested, as one possible mechanism, interaction between Gal repressors bound at these operators. Schleif and co-workers³ similarly discovered that complete repression of the araBAD operon depends upon an operator site to which the regulatory protein AraC binds, located some 200 base pairs upstream of the transcription start site. They deduced that the AraC protein bound to the upstream operator interacts with another protein bound near the transcriptional start site, the intervening DNA looping to allow the interaction. This conclusion followed from the remarkable observation that efficient repression was maintained when an integral number of helical turns of DNA was added or deleted between the operator and the gene, but not when the spacing was varied by half-integral numbers of turns. They reasoned that proteins separated by the relatively short distance of a few

hundred base pairs can interact by simple looping only if located on the same side of the helix; introduction of half-integral turns would place the proteins on opposite sides of the helix and the energy required both to bend and twist the DNA would be prohibitive. Schleif and colleagues^{4,5} have since presented additional evidence consistent with the idea of DNA looping.

The ideas discussed above have recently been extended to the case of a mammalian virus, in particular the early gene promoter of simian virus 40 (SV40). This promoter contains three adjacent sets of sequences that influence transcription: the 'TATA' region near the transcription start site; a middle segment of 60 base pairs called the 21-base-pair repeats; and further upstream the enhancer, covering some 150 base pairs. Efficient transcription evidently requires that proteins bind to each of these segments. Takahashi et al.6 report that the insertion of 5 or 15 base pairs between the enhancer and the middle segment decreases transcription in vivo more drastically than does insertion of 10 or 21 base pairs. Similar results have been found for insertions between the middle segment and TATA. The former result is particularly striking because the enhancer functions even when re-positioned hundreds of base pairs from the middle segment. A simple interpretation of these experiments is that proteins bound to the enhancer contact other proteins bound to the middle segment and that these in turn contact a protein bound at TATA. When the enhancer is re-positioned at a distance (and perhaps in the normal position as well) the DNA presumably loops to allow the interaction to take place.

Our most direct demonstrations of interaction between adjacent DNA-bound proteins and between separated proteins with concomitant DNA looping come from studies of the λ -phage repressor. Figure 1 and its legend summarizes several aspects of the structure and activities of this protein. Briefly, the repressor, which can activate as well as repress transcription. normally binds to two adjacent sites on the λ chromosome. A repressor dimer bound at the stronger of the two sites helps a second dimer bind to the weaker site. This cooperative binding, which depends upon contact between the proteins, increases the affinity of the weaker site some 10-fold. The repressor at the weaker site then directly contacts RNA polymerase and helps it to bind and begin transcription of the adjacent gene. At each operator site, repressor is bound along one face of the helix (for a review see ref. 7).

Thus, interacting λ repressors normally lie adjacent to each other on the DNA; our recent experiments show that they also interact when separated. Hochschild and I⁸ used the technique of 'DNase footprinting' to show that λ repressor binds cooperatively to operator sites separated by approximately integral numbers of turns (five, six and now seven). Just as when the sites are in their normal positions, binding to the strong site increases binding to the weak site some 10-fold. In contrast, cooperative binding to operators separated by, for example, 6.5 turns was observed only if a four-base gap was introduced into

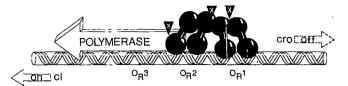

Fig. 1 Action of λ repressor. The λ repressor is both a negative and a positive regulator of gene expression. When bound to the right operator on the phage chromosome (O_R) , the repressor shuts off (rightward) transcription of a gene required for lytic growth (cro) and, simultaneously, activates (leftward) transcription of its own gene (cI). Repressor bound to the strong site O_R1 helps another repressor bind to the weaker adjacent site $O_R 2$ and this arrangement activates expression of the repressor gene as follows: the repressor at $O_{\rm p}2$ contacts polymerase and thereby helps it bind and begin transcription at the adjacent leftward promoter. At the same time rightward transcription is repressed because the bound repressors prevent polymerase from binding to the rightward promoter. Three protein-protein interactions are indicated by 'X' in the figure: each repressor dimer, the DNA-binding species, is held together primarily by contacts between carboxyl domains; interactions between carboxyl domains are also responsible for cooperative repressor binding to adjacent operator sites, but it is an amino domain of the repressor dimer at $O_R 2$ that contacts polymerase at the adjacent promoter. If the concentration of repressor increases transiently, site O_R 3 becomes occupied by a third repressor dimer and transcription of the repressor gene is turned off. (See ref. 7)

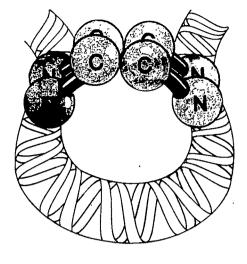

Fig. 2 λ repressors bound to two operator sites separated by seven helical turns. Although the precise points of contact between the dimers seem different from those indicated in Fig. 1, we suspect that either flexibility of the protein or some modification in the path of the DNA allows similar interactions in both cases⁸.

one of the DNA strands between the sites. This alteration presumably increases the torsional flexibility of the DNA and facilitates twisting, so that the proteins can be apposed. Whether the operator sites are adjacent or separated, cooperative binding of λ repressor depends upon the carboxyl domain of the protein, which does not contact DNA. These and other results suggest that λ repressors bind cooperatively to separated operator sites just as they do to adjacent sites, the DNA in between bending smoothly to accommodate the interaction as indicated in Fig 2.

The idea that cooperative binding of λ repressor to separated sites induces a smooth bend in the DNA plausibly accounts for the following observation: as repressor binds, the DNA between the sites becomes alternately hypersensitive and resistant to DNase, the interval separating these recurring hypersensitive and resistant sites being five base pairs. We imagine that in the DNA between the bound repressors, the minor groove (the site recognized by DNase) is expanded along the outside surface of the loop and compressed along the inside surface (see Fig. 2), thereby periodically changing the DNase sensitivity. The pattern of DNase sensitivity resembles that observed with DNA wrapped around a protein⁹⁻¹¹ or in a nucleosome¹², but as confirmed by the electron microscopy experiments I describe below, the looped DNA in between the sites is not in contact with repressor. Perhaps the DNase-hypersensitive sites found near active genes in eukaryotic chromosomes¹³ are regions of distorted DNA structure caused by looping.

In collaboration with J. Griffith, we have now used electron microscopy to provide direct visual evidence for DNA looping induced by λ repressor binding¹⁴. The pictures show λ repressors bound to DNA fragments bearing two λ operators separated by 5 helical turns, measuring from the centres of the sites. The repressors are evidently in contact, the DNA in between looped out. The looped structures are not seen if the spacing between the operator sites is 4.5 or 5.5 helical turns. The results reinforce our conclusion that the bound repressors interact only if the operators are positioned so that the repressors are on the same side of the helix, a finding consistent with the assumption that the energy needed to twist DNA one-half turn (and thereby align repressors fixed to opposite sides of the helix) is prohibited.

Cooperative binding of λ repressors to separated sites, with concomitant DNA looping, requires no special DNA sequences

(as far as we know) and is readily observed on linear DNA under roughly physiological conditions using purified repressor and DNA. The repressor is not specially designed for looping because, as noted above, the operator sites are immediately adjacent on the ordinary λ chromosome. We do not yet know how increased separation between the sites (beyond seven turns) will affect the reaction, nor do we yet know whether supercoiling the DNA, or adding nonspecific DNA-binding proteins (for example, the HU protein of E. coli, or histones) will facilitate or hinder the reaction. Unpublished experiments (A. Hochschild and M.P., in preparation) show that the cooperative binding to separated sites observed in vitro can also be detected in vivo using appropriately designed DNA molecules.

New cases of gene regulation at a distance in bacteria are now coming to light^{15,16}. Even the Lac repressor, long thought to be a paradigm of single-site binding, can bind cooperatively to separated sites and there is some evidence that this binding may be physiologically important (J. Gralla, B. Muller-Hill, personal communications; see also ref. 17). Although there are cases involving the non-cooperative binding of regulatory proteins (for example the λ Cro protein) they may prove to be the exceptions. I have argued elsewhere that cooperative DNA binding of regulatory proteins is a useful strategy for increasing the specificity of DNA-protein interactions and for constructing sensitive genetic switches⁷. In some cases the protein binding sites are adjacent (as is ordinarily the case in λ and SV40) and in other cases they are separated, DNA looping allowing the same interactions as when the proteins are adjacent. Perhaps we have here another example of a common motif: viruses use their DNA more economically than do cells.

I now consider alternative models designed to explain action at a distance. Various experimental results, all consistent with looping, argue against the alternative models.

Twisting

One version of this model would have regulatory proteins bind directly to some altered form of DNA, for example left handed or single stranded; another version imagines that the regulatory protein has an enzymatic activity that alters DNA conformation, for example by unwinding it. Gene activation would then be a

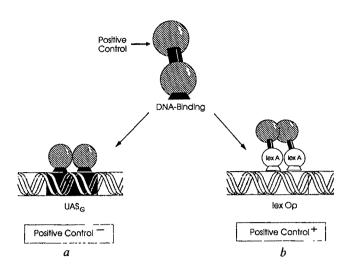

Fig. 3 Separation of the DNA-binding and positive control functions in a eukaryotic transcriptional regulator. The top line imagines the yeast activator GAL4 as consisting of two domains, the amino domain which recognizes sequences in the galactose upstream activating sequence (UAS_G) and the carboxyl domain which, when bound to DNA through the amino domain, contacts another protein to mediate positive control. In a, the carboxyl domain has been removed; this fragment recognizes UAS_G but fails to activate transcription. In b, the DNA-binding domain has been replaced with that of the bacterial protein LexA. This protein activates transcription in yeast if a lexA operator is positioned near the start site of a gene. The proteins are shown as binding to DNA as dimers but we are not certain this is correct^{25,26}.

consequence of conformation changes propagated through the DNA which allow other proteins to bind and begin transcription. The following considerations argue against these views.

A large number of known or suspected DNA-binding regulatory proteins have been isolated from both prokaryotes and eukaryotes and there is good reason to believe that all recognize ordinary helical DNA. For one class of these proteins, exemplifted by λ repressor, the structure of the protein-DNA complex is known. Each of these proteins bears protruding α -helices that fit into the DNA major groove and make sequence-specific contacts with functional groups exposed along the edges of base pairs. As expected, these proteins do not greatly alter the structure of DNA upon binding (see ref. 18, for example). Other transcriptional regulators probably recognize specific DNA sequences using probes other than α -helices (see, for example, ref. 19) but there is no hint that these proteins recognize greatly altered forms of DNA. The known regulatory proteins recognize their sites in linear DNA with binding constants that approach those that describe the well-characterized Lac or λ repressoroperator interactions. Were these proteins to recognize some greatly altered DNA structure, this result would not have been

One specific suggestion, namely that enhancer sequences are recognized as a form of left-handed DNA called Z-DNA²⁰, now appears to be incorrect. Mutational analyses of enhancers fail to confirm the simple prediction that alternating purines and pyrimidines, the likeliest Z-forming sequences, are required for enhancer function²¹. The presumed correlation between active genes and Z-DNA in *Drosophila*, suggested by experiments with antibodies, has been demonstrated to be an artefact of sample preparation²².

If a transcriptional regulator does not change DNA structure, how does it activate transcription? For the case of λ repressor we know the answer: one surface of repressor contacts DNA and another contacts RNA polymerase and activates gene

expression. An important argument supporting this picture was the isolation of mutant λ repressors (called pc for positive control) that bind DNA normally but that fail to activate transcription²³. The changed amino acids in these mutants are found on that surface of repressor that had been predicted, on independent grounds, to approach most closely the adjacent RNA polymerase. The properties of these mutants thus show that although DNA binding of repressor is necessary for gene activation, it is not sufficient; an additional site, presumably a site of contact with polymerase, is also required.

We have extended these ideas to a eukaryotic case, showing that the DNA-binding and gene activation functions of a yeast transcriptional regulator can be separated. The protein we study, GAL4, activates transcription of the GAL genes in the presence of galactose. The protein binds to sequences in a control element called the UAS_G (the galactose upstream activating sequence) and activates transcription at sites about 250 base pairs away in wild-type strains and as far as 750 base pairs away in modified strains²⁴.

Figure 3 shows the properties of two fragments of GAL4, one of which (a) bears the GAL4 DNA-binding function and the other of which (b) bears the activation function. Protein fragment a, consisting solely of the first 98 amino acids of GAL4, binds the GAL4 recognition sites as assayed in vitro and in vivo but fails to activate transcription. A hybrid molecule bearing the amino-terminal portion of GAL4 fused to β -galactosidase has similar properties. These GAL4 derivatives, lacking aminoacid sequences from the carboxyl end of the molecule, are formally equivalent to the pc mutants of λ repressor²⁵. Protein b, bearing the carboxyl 800 amino acids of GAL4 attached to a DNA-binding domain of the bacterial repressor LexA, acts as a positive regulator in yeast in the absence of the ordinary GAL4 recognition sequences. The hybrid protein binds to lexA operators but not to UASG and its activity as a positive regulator requires that a lexA operator be positioned near the transcription start site of the gene²⁶.

These experiments argue that, for GAL4 as for λ repressor, the role of DNA binding is to position the protein on the DNA so that it can use some other activity to stimulate transcription. Although there is no indication that GAL4 itself can twist DNA, none of these experiments excludes the possibility that GAL4 helps some other protein to bind adjacent to UAS $_G$ and that that protein activates transcription by untwisting (or twisting) DNA. However, the following experiment, performed with a mammalian virus, argues against this possibility.

Plon and Wang²⁷ have designed an incisive experiment that topologically separates the DNA site recognized by a regulatory protein (or proteins) from a gene without destroying gene activation. They constructed a 'tailed circle' (see Fig. 4) in which the regulatory sequence (the SV40 enhancer) forms a hairpin protruding from an otherwise intact circular DNA molecule that includes a gene (human β -globin). The strong result is that, when this construct is introduced into cells, transcription of the gene is enhancer dependent, as it is when gene and enhancer are disposed on ordinary DNA molecules. Thus, twisting of the enhancer cannot be responsible for gene activation, because twisting the protruding enhancer could have no effect on the topology of the gene.

Sliding

In this model a protein recognizes a specific site on DNA and then moves (slides, tracks) along the DNA to another specific sequence where, perhaps by interacting with another protein, it initiates transcription. Another version of essentially the same idea imagines that the regulatory protein remains bound at the original site and the DNA is threaded past or through the bound protein until the second critical site is encountered. (I am restricting the discussion to cases involving communication between two specific DNA sites. Where one specific and one nonspecific

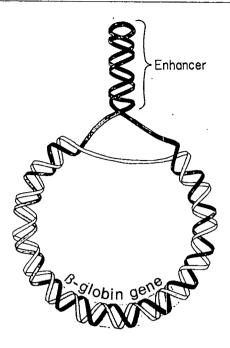

Fig. 4 The 'tailed circle' consists of an enhancer linked to, but topologically separated from, a gene. One of the DNA strands of this plasmid bears two copies of an SV40 enhancer sequence, one copy inverted with respect to the other. This extra region protrudes from the circle and self-pairs to form a functional enhancer. The main body of the circle contains the β -globin gene, transcription of which is increased by the enhancer. Twisting of the enhancer has no effect on the winding of the strands on the main body of the circle; nevertheless, the enhancer efficiently increases β -globin transcription²⁷.

site are involved, for example in the action of type I restriction enzymes, sliding may operate²⁸.)

No experiment involving transcriptional regulation, to my knowledge, directly argues against the sliders. But the strongest presumed example of bona fide sliding has been convincingly reinterpreted in the light of recent experiments. The cases in point involve two examples of site-specific recombination in bacteria. Both illustrate a remarkable common property of various site-specific recombination systems: two sites separated by many thousands of base pairs recombine only if the two sites are in a specified orientation; if one of the sites is inverted with respect to the other no recombination is observed. How does a protein bound at one site 'sense' the orientation of another which is 50,000 base pairs away? Tracking seemed a reasonable explanation and this mechanism could explain other experimental findings²⁹.

Craigie and Mizuuchi³⁰ have now eliminated tracking as a mechanism for site-specific recombination involving the ends of the bacteriophage Mu. This recombination reaction proceeds in vitro at high efficiency with purified proteins and ATP. Craigie and Mizuuchi³⁰ show that two Mu sites not on the same DNA molecule can nevertheless recombine if they are part of separate molecules that are intertwined (Fig. 5); in this case a protein could not track from one site to the other. These findings are consistent with tests of the tracking model involving the bacterial transposon Tn3, in which Benjamin et al.³¹ used electron microscopy, as well as other techniques, to analyse products of recombination in vitro. They found a distribution of structures inconsistent with the tracking model.

Boocock et al.³² have also described experiments which strongly support the idea that the ends of Tn3 find themselves by looping, and they have described a plausible model, which I shall not review here, that explains the orientation dependence

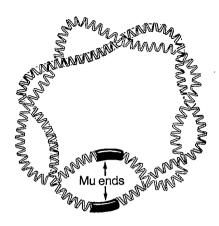

Fig. 5 Two intertwined DNA circles show that recombination is possible without tracking. Each line represents a double-stranded DNA molecule and each bears a Mu phage end. These sites efficiently recombine in vitro under the direction of site-specific recombination proteins. Because the sites are on separate molecules, it is impossible to travel from one to the other by tracking³⁰.

of the reaction. These findings help to unify our understanding of site-specific recombination; in another case, that involving the ends of the λ prophage, it is already well accepted that the sites find each other by looping^{33,34}.

Oozing

The simplest form of this model is that the binding of a regulatory protein to its operator helps binding of another protein to adjacent sequences, which in turn helps another to bind next to it, and so on, until a procession of proteins has oozed out from the control sequence to the gene where transcription is initiated. This idea as applied to transcription cannot be discounted entirely, and indeed some oozing around the control sequence or around the transcription start site seems a possibility (see, for example, the line-up of proteins in Fig. 1). But it seems implausible to imagine such an effect working over thousands of base pairs. The idea under consideration here should not be confused with nonspecific wrapping of DNA around histone-like proteins.

Oozing is not important for site-specific recombination. Experiments performed *in vitro* show that for the case involving the ends of Tn3, the amount of protein sufficient to catalyse the reaction is insufficient to cover the DNA between the sites³⁵.

Generalizations

If the thrust of these arguments is correct, we have the outlines of a unified view of gene regulation. In its simplest form this view would make two statements. First, regulatory proteins recognize specific sequences in DNA using structures that are complementary to the ordinary helix. The α -helix that protrudes from the surface of λ repressor and explores functional groups exposed in the major groove of DNA is an example of such a structure. Second, DNA-bound regulatory proteins influence transcription by excluding binding of other proteins (for example by competing with polymerase for an essential site) or, more generally, by touching another DNA-bound protein. In the λ case, for example, one DNA-bound repressor helps another to bind, and the latter in turn helps polymerase to bind and begin transcription, and these cooperative effects are mediated by protein-protein interactions. The point I have explicitly argued in this review is that these descriptions hold whether the interacting proteins are adjacent on DNA or whether they are separated—in the latter case the DNA in between the separated sites loops out to allow the protein-protein interactions.

Should looping prove to be a general phenomenon in gene regulation at a distance, it is not difficult to imagine how various forms of positive and negative control might be effected. For example, a protein bound to a distal site might help another protein bind to a proximal site and the latter might then directly activate or repress a gene. Alternatively, a bound activator protein might be constrained and rendered inactive by interaction with another protein bound at a distal site. Proteins binding within the loop might break it, thereby relieving the negative or positive effect of the interaction. Proteins bound to the same DNA sites might have quite different effects on gene regulation depending upon the nature of their interaction with other proteins. Our problem is no longer to invent a possible mechanism; rather, it is to see how far one operative idea, looping, will

Melting history of Antarctica during the past 60,000 years

L. D. Labeyrie, J. J. Pichon, M. Labracherie, P. Ippolito, J. Duprat[†] & J. C. Duplessy^{*}

* Centre des Faibles Radioactivités, Laboratoire Mixte CNRS/CEA, Domaine du CNRS, 91190 Gif-sur-Yvette, France † Département de Géologie et Océanographie, L. A. 197, Université de Bordeaux 1, Avenue des Facultés, 33405 Talence, France

Marked changes in the surface-water hydrology of the Southern Ocean during the past 60 kyr are revealed by a detailed comparison of the oxygen isotopic composition of planktonic and benthic foraminifera from sediment cores and the surface-water temperature estimated by a transfer function derived from the distribution of diatoms in the same sediments. From 35 to 17 kyr BP, the Southern Ocean polar front was covered by a melt-water lid containing a significant contribution from melting icebergs, calved from Antarctic ice shelves. These icebergs may have originated from a succession of surges of the ice shelves.

THE melting history of Antarctica during the most recent climatic cycle is a challenging problem which has an important bearing on global climatic models¹, on the formation of bottom and intermediate water, and consequently on the CO2 content of the atmosphere². One open question is the possibility of large surges of part of the Western Antarctic ice sheet3. Such abrupt events should be detectable using the oxygen isotopic composition of fossil planktonic foraminifera or other epipelagic organisms, because Antarctic ice, due to its conditions of accumulation, is depleted by 35-50% in δ^{18} O compared to mean ocean water. However, as the foraminiferal isotopic ratio is a function of both the temperature and the isotopic composition of the surrounding water, we must estimate the water temperature independently. Imbrie and Kipp4 have shown that surface-water temperature may be accurately estimated by transfer functions based on quantitative micropalaeontological analyses. Using a transfer function derived from Southern Ocean diatoms⁵, we may estimate independently the two components of the oxygen

isotopic record of the epipelagic foraminifera. The oxygen isotopic ratio of the benthic foraminifera analysed at the same levels in sediment cores gives the fraction of the sea-water isotopic changes which affects the whole water column, this being connected with the evolution of the continental ice sheets. We may thus estimate the local surface-water isotopic changes. We present here the results of such a study, carried out on two sediment cores from the southern Indian Ocean which cover the period including isotopic stages 3 and 2 of the last glacial (ref. 6), and the following deglaciation.

¹⁸O results and chronology

The cores MD73026 (44°59' S, 53°17' E) and MD84527 (43°49' S, 51°19' E) are located in the high-productivity belt north of the Crozet Plateau. Their position within the polar front system⁷, the major boundary between subtropical and Antarctic surface waters, makes them ideal for a study of hydrographic changes in the Southern Ocean. The high sedimentation rate

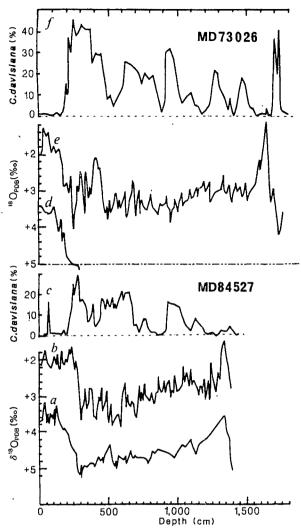

Fig. 1 a-c, Records from core MD84527 (43°49.3′ S, 51°19.1′ E; 3,262 m depth). a, δ^{18} O (in parts per 10³, relative to the PDB standard) (δ^{18} O = [($R_{carbonate}/R_{standard})$ - 1]×10³, where R = { 18 O/ 16 O}) of the benthic foraminifera Cibicides wuellerstorfi, plotted against depth in the core (corrected by +0.64% to take into account the specific fractionation⁴⁸). b, δ^{18} O_{PDB} for the planktonic foraminifera Neogloboquadrina pachyderma l.c. c, In the same core, relative amount of the radiolarian species Cycladophora davisiana. d-f, Records from core MD73026 (44°59′ S, 53°17′ E; 3,429 m depth). d, δ^{18} O_{PDB} of the benthic foraminifera Nonion sp., corrected by +0.4% for specific fractionation. e, δ^{18} O_{PDB} for N. pachyderma l.c. f, In the same core, relative amount of C. davisiana.

 $(>8~{\rm cm~kyr^{-1}})$ has provided a highly detailed record of the most recent climatic cycle. We have analysed in these cores the oxygen isotopic ratio of the epipelagic foraminiferal species Neogloboquadrina pachyderma left-coiled and, wherever possible, the benthic species Melonis barleanum and Cibicides wuellerstorfi. We have also analysed the foraminiferal δ^{13} C and the diatom δ^{18} O values, the diatom, foraminiferal and radiolarian specific abundances, and the abundance of ice-rafted detrital grains (L.D.L. et al., in preparation). Figure 1 shows the relative abundance of the radiolarian species Cycladophora davisiana, a good stratigraphic marker in the Southern Ocean^{8,9}, together with the foraminiferal δ^{18} O values, as a function of depth in the cores. These records are similar to the published records of nearby cores MD73025¹⁰⁻¹² and RC11-120⁸, if we take into account the varying sedimentation rates.

We have referred the records of MD84527 and MD73026 to the SPECMAP time scale¹³, based on RC11-120, to allow a

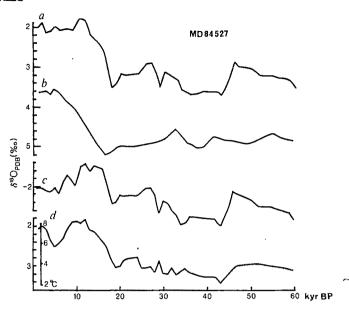

Fig. 2 Records from core MD84527, plotted against time. a, Planktonic isotopic record; b, benthic isotopic record; c, local isotopic changes (δ^{18} O (planktonic) – δ^{18} O (benthic)), expressed on the same timescale. A correction factor of +0.4% has been added to all the values in the period 0-9 kyr BP to correct for the effect of bottom-water temperature change (see text). d, Surfacewater temperature change at the location of the core. To allow direct comparison with the other records, the isotopic effect of these temperature changes is plotted on the δ^{18} O scale of N. pachyderma, using the calibration of Table 1.

better comparison between them and with other records. This has been done by adjusting, at each depth level in the three cores, the foraminiferal $\delta^{18}O$ and $\delta^{13}C$ values, and the relative abundance of *C. davisiana*. The accuracy of the correlation is better than 1 kyr during deglaciation, but only 3-5 kyr for isotopic stages 2 and 3. This is not critical for the present study.

The benthic foraminiferal record of core MD73026 covers' only the period from 0 to 18 kyr BP. However, whereas the North Atlantic Ocean experienced significant deep-water temperature changes during the most recent glacial period¹⁴, the isotopic records of benthic foraminifera during the most recent climatic cycle are congruent in the Indian and Pacific Oceans¹¹. We have therefore used the δ^{18} O record of *C. wuellerstorfi* in core MD84527 as a reference for core MD73026. The resulting foraminiferal δ^{18} O records of cores MD84527 and MD73026 are plotted against age in Figs 2 and 3.

The surface-water isotopic signal

Significant differences in the isotopic records of the planktonic and benthic foraminifera are evident in both cores. Note in particular the earlier (by 2-3 kyr) decrease in the isotopic ratio of the planktonic foraminifera during deglaciation (17-10 kyr BP), and the anomalously low isotopic ratio of these foraminifera before and during the glacial maximum (35-17 kyr BP). Such differences also exist in the nearby core MD73025¹⁵. The sediments in these three cores are not obviously disturbed, and they contain normal records of the other stratigraphical indexes (benthic foraminifera δ^{18} O, radiolarian species *C. davisiana* and diatom species *Eucampia antarctica*). The effects of bioturbation on the isotopic records have been recently quantified by ¹⁴C dating of the same monospecific samples used for isotopic analyses¹⁶; we conclude that bioturbation cannot explain the observed isotopic anomalies.

The differences in the isotopic records between surface (planktonic) and deep (benthic) foraminifera must be explained by

Table 1 Data used for calculations of oxygen isotopic fractionation between N. pachyderma and water

Sample	Lat.	Long.	S (%)	$\delta^{18} {\rm O}_{ m water}$	T (°C)	$\delta^{18}O_{pachy}$

 $8^{18}{\rm O_{PDB}}$ of the planktonic foraminifera N. pachyderma sen. in samples extracted from core tops, and a single sediment trap sample (M269-965)⁴⁵. The temperatures (T) and salinities (S) are the mean summer values extracted from atlases^{46,47} for 80-100 m water depth at the sample locations. The water $8^{18}{\rm O}$ values are calculated from the salinities²³.

differences in the evolution of the surface and deep waters in the Southern Ocean during the past 60 kyr. Both the temperature and the isotopic composition of the waters may be involved. and these must be estimated independently. Duplessy et al. 10 have used the benthic record of MD73025 as a reference for global sea-water isotopic changes during the accumulation and melting of the continental ice sheets. More recent results14 indicate that of the 1.6% total isotopic difference between the last glacial maximum and the Holocene in that core, 0.4% has to be attributed to a 1.5 °C warming of the deep Indian Ocean water at ~9 kyr BP, when the present mode of formation of the North Atlantic Deep Water developed. Accordingly, we adopt the benthic foraminiferal record of core MD84527 for the past 60 kyr as a reference for the isotopic record for mean ocean water, after correcting by +0.4% all isotopic values from the period 0-9 kyr BP. By subtracting the corrected benthic signal from the N. pachyderma records of MD84527 and MD73026, we obtain the 'local' isotopic records for the planktonic foraminifera (Figs 2c, 3c).

These records integrate the effect of the surface-water temperature change on the isotopic fractionation during carbonate precipitation. The first step in estimating this effect is to reconstruct the temperature changes during the past 60 kyr at the location of the cores. This has been done using a transfer function derived by multivariate correlation⁴ between the diatom specific abundance in Holocene core tops from the Southern Ocean and the present surface-water temperature at the location of the cores⁵. The summer (February) surface temperature is calculated by this method with an accuracy of ± 1.1 °C.

The temperature records obtained by this method (Figs 2d, 3d) show two interesting features. First, the increase in surfacewater temperature preceded by $\sim 2-3$ kyr the changes in isotopic ratio of the benthic foraminifera, which marks the initiation of the Northern Hemisphere deglaciation. This confirms the results of Hays et al.¹⁷, who have shown that the temperature maximum in the Southern Ocean core RC11-120 was near 9.4 kyr BP, that is, leading by ~ 2 kyr the Northern Hemisphere Holocene optimum. Secondly, the summer temperature was fairly stable in core MD84527 (between +2 and +4.5 °C) throughout the period 17-60 kyr BP. This means that the Antarctic polar front remained at the latitude of this core throughout this period. The temperature record of MD73026 is presently available only until 35 kyr BP, thus limiting the quantitative interpretation of the isotopic anomaly in that core.

The temperature dependence of the oxygen isotopic fractionation during carbonate precipitation in *N. pachyderma* was obtained by comparing *N. pachyderma* isotopic analyses from 12 Holocene core tops with the present summer water temperature at the location of these cores (Table 1). The depth

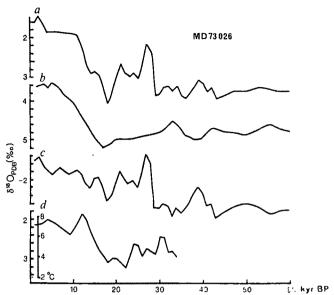

Fig. 3 8¹⁸O_{PDB} of the foraminifera in core MD73026, plotted against time. a, Planktonic foraminifera N. pachyderma 1 c.; b, benthic record of core MD84527; c, local isotopic changes for core MD73026 (as for Fig. 2c); d, summer surface-water temperature changes at the location of the core (as for Fig. 2d).

habitat of this species in low-productivity areas is in the 80-100 m range¹⁸, of the same order or slightly deeper than that of the diatoms¹⁹. In the higher-productivity area of the North Pacific, *N. pachyderma* 1.c. occupy the entire surface mixed layer²⁰. Regression analysis over the temperature range -1 to +9 °C yields $\delta^{18}O_{pachy} - \delta^{18}O_{water} = 3.84 - 0.25 T$ with 1σ errors of 0.12 in the constant and 0.03 in the slope. These results are in agreement with the estimate of Shackleton²¹ for benthic foraminifera living in this temperature range. Using the relationship obtained for *N. pachyderma*, we may now calculate the isotopic changes which would have been due solely to the changes in water temperature. The corresponding $\delta^{18}O$ scales are reported beside the temperature scales in Figs 2d and 3d.

The variations of the surface-water δ^{18} O have been calculated by correcting the local isotopic records of the planktonic foraminifera (Figs 2c, 3c) for the effect of temperature changes. These estimates of the net surface-water isotopic changes are shown in Fig. 4a, b. Although there is some variability, the general trend in the signal corresponds to a negative shift in the surface-water isotopic ratio for the entire glacial period compared to the present. Several shifts of large amplitude (1%) occur between 17 and 30-35 kyr BP; these are particularly evident in core MD73026 (Fig. 4a).

Low- δ^{18} O water from melting icebergs

Several mechanisms may be invoked to explain the decrease in the surface-water isotopic ratio. There is today a 0.4% negative gradient in the surface-water isotopic ratio from north to south through the Antarctic polar front^{23,24}. The subtropical water is enriched in ¹⁸O by evaporation (+0.2% relative to standard mean ocean water, SMOW), and surface Antarctic water is depleted by excess precipitation (-0.2%). Studies in progress using global climatic models with isotopic tracers indicate that neither this isotopic gradient, nor the precipitation over the Southern Ocean. could have increased significantly during the most recent glacial (J. Jouzel, in preparation). We have therefore to look for a source of water with a much lower isotopic ratio than that of the rain and snow which today fall over the Southern Ocean Melting sea ice is of no effect, because there is very little isotopic fractionation during freezing of sea water²⁵. On the other hand, melting icebergs could be of significant influence; their isotopic ratio, depending on the source of ice within Antarctica, he-

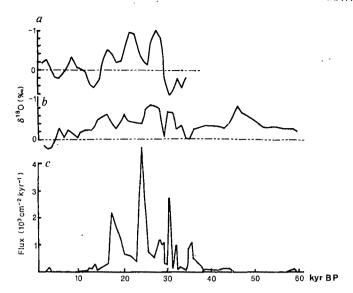

Fig. 4 a, b, Net surface-water isotopic variations for cores MD73026 (a) and MD84527 (b), obtained by subtraction of the surface-temperature signal from the local isotopic changes. c, Absolute fluxes of glacial detrital quartz grains in core MD84527.

between -35 and -55% (ref. 25). To date, however, such an input of iceberg melt water has been measured only along the Filchner Ice Shelf, in the Weddell Sea²⁵. To explain the isotopic anomalies, we must therefore consider periods of major increase in the production and melting of icebergs during the last glacial.

The first piece of evidence in support of this hypothesis is the distribution of ice-rafted detritus (IRD). The relationship between glaciation and the abundance of IRD in the sediments of the Southern Ocean is well known^{9,26-28}. Keany et al.²⁸ have connected the north-south shifts in IRD deposition to the northsouth shifts in the iceberg melting zone. Although a large part of the IRD deposited between the Scotia Sea and Kerguelen Islands consists of tholeitic glass shards transported by sea ice and icebergs from the South Sandwich Islands^{26,27}, quartz and chlorite probably originate only from the old continental crust of Antarctica. Their incorporation in icebergs could have been facilitated by the extension of the grounded ice shelves over the continental margins. To test for a possible increase in the amount of IRD transport by Antarctic icebergs, we have estimated the fluxes of quartz grains during the last glacial in core MD84527. We sub-sampled known sediment volumes, and counted all the quartz grains in the size fraction larger than 63 µm, thereby excluding wind-transported detritals. As shown in Fig. 4c, the quartz flux increases dramatically during the period from 17 to 35 kyr BP, that is, at the time of the major isotopic anomaly in both cores. Small differences in the relative depths of the IRD maxima and isotopic anomalies may be explained by several factors. The sampling for isotopic and IRD studies was done on separate occasions, at different levels in the core. Furthermore, the wet density of the IRD is much higher than for foraminifera and diatoms, thus allowing for differential settling of a few centimetres within the water-rich upper sediment before compaction. The earlier isotopic anomaly (at ~50 kyr BP) recorded in core MD84527 but not in the planktonic record of core MD73026 (Figs 2a, 3a) does not correspond to any significant increase in detrital quartz.

Other observations may help to explain the surface hydrography during these periods. Cooke and Hays⁹ have remarked that during the last glacial maximum (broadly defined as the *C. davisiana* zone b), IRD fluxes were large in both the Atlantic and south-west Indian sectors of the Southern Ocean. Before this time (*C. davisiana* zones c-d, ~40-60 kyr BP), the area of large IRD fluxes was limited to the Atlantic sector, a result

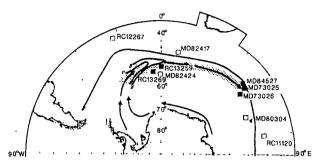

Fig. 5 Distribution of the surface-water isotopic anomaly at 18-20 kyr BP. ■, Cores containing the anomaly in the planktonic foraminifera or diatom records²²; □, cores with normal isotopic records; →, estimated trajectory of the icebergs extrapolated from present trajectories⁴⁹; —, position of the polar front at 18 kyr BP. The shading indicates regions of high loadings at 18 kyr BP for factor 2 of Burckle's diatom factorial analysis, which is mostly composed of E. antarctica, and indicates surface-water low salinity from melting sea-ice and icebergs.

which agrees with our quartz flux study. However, for both these periods, and in the different sectors, there was a significant increase in the relative amount of C. davisiana. In its present habitat in the Okhotsk Sea, this species is associated with specific hydrographic conditions, namely a surface water lid of less saline water with a strong temperature minimum near its base, and the formation in winter of sea ice which melts in the summer²⁹. Morley and Hays²⁹ have proposed this hydrological situation as a modern analogue for the periods of high abundance of this radiolarian, and specifically for the last glacial in the Southern Ocean. The diatom Eucampia antarctica is abundant today around the Antarctic peninsula. Burckle³⁰ associates this species with neritic and/or low-salinity waters (melting sea ice and icebergs). The surface-water conditions favourable for its development are thus the same as those for C. davisiana. Burckle³⁰ interprets the distribution of E. antarctica in the sediment of the last glacial maximum around Antarctica as indicating an extension of a low-salinity belt south of the polar front. In our set of cores, there is also a good correlation between the relative abundance of C. davisiana (Fig. 1), several species of diatoms (E. antarctica and Thalassiosira antarctica) and the isotopic anomalies²². Figure 5 shows the distribution of the E. antarctica factor of Burckle³⁰, together with the cores with and without the isotopic anomaly, at ~18 kyr BP. This distribution corresponds to the high IRD fluxes at that period9. We interpret this data to be an indication of the trajectory of melting sea-ice and icebergs from the Weddell Sea south of the polar front, along the circumpolar drift. With this hypothesis, the lack of detrital quartz and other IRD in the south-west Indian sector during the surface-water isotopic anomalies of the 40-60 kyr BP period would indicate that most of the icebergs melted faster at that time, within the Atlantic sector. Cooke and Hays consider that sea ice was more restricted at ~50 kyr than at 18 kyr BP, thus allowing faster melting: We do not have data to substantiate this argument, and therefore will not discuss this early part of the last glacial.

The magnitude of the ice flux from Antarctica necessary to give the 1% isotopic anomaly may be estimated from Fig. 5. Assuming that the ice isotopic ratio was -40%, the water mixed-layer thickness during periods of melt-water input was 60 m, and the surface covered by the melt water was 2×10^6 km² (30° W to 60° E, by 4° latitude), we need 10,000 km³ of melt water from Antarctic ice. This number should be compared with the present-day volume of 2,000 km³ melt water produced annually from melting Antarctic ice (refs 31, 32). It is not possible, therefore, to attribute the isotopic anomalies recorded during the last glacial to a regular calving, at the present rate, of icebergs from the ice shelves.

A much larger accumulation rate of the Antarctic ice sheet during the last glacial is most unlikely. The ice flow models developed to explain the data from the Dome C33 and Vostok34 ice cores imply a smaller ice accumulation rate during the last glacial. This is confirmed by the higher ¹⁰Be specific activity observed in the Vostok ice core at that time35. The higher gas content of the Bird ice core during the last glacial maximum also indicates a lower altitude of ice formation in the central part of the West Antarctic ice sheet³⁶. There are conflicting land-based geological observations suggesting that the ice sheet could have had a larger extension and was also thicker at the periphery during the last glacial³⁷. It is thus possible that during at least part of the last glacial, accumulation rates were significantly larger than today around the periphery of Antarctica, but not in the more central parts. Taking into account the estimated volume of the total Antarctic ice sheet during the glacial period of 3.67×10⁷ km³ (ref. 38), an erosion rate of ~10⁴ km³ yr⁻¹ could not be sustained for several kyr without being recorded in the Dome C and Vostok cores. The constraints are not so strong for the West Antarctic ice sheet. The lower altitude of ice accumulation during the glacial³⁶ could be interpreted as being due to a greater erosion rate than at present. Additional contributions from icebergs from the coastal ice sheets of the Antarctic Peninsula and the South Shetland and South Orkney Islands³⁹ are probable, but not quantifiable. Moreover, due to their proximity to the evaporation zones, these small ice caps probably had oxygen isotopic ratios similar to that of normal precipitation and therefore had a minor effect on the observed isotopic anomaly.

These arguments lead us to conclude that erosion of the Antarctic ice sheet could not have produced the volume of icebergs necessary to induce the observed isotopic anomalies as a more-or-less permanent regime during the last glacial. However, the detailed record of core MD73026 (Fig. 4a) does indicate that the ice output was irregular, with three well-defined peaks, one approximately every 6 kyr. We do not have a sufficiently precise chronology to estimate the duration of each melt-water event. The chronostratigraphy used in Fig. 3 is defined by a small number of references to the SPECMAP timescale (18, 21, 29, 35, 43 and 57 kyr BP, for isotopic stages 2 and 3), with the sedimentation rate taken as constant within each interval. However, Cooke and co-workers^{26,40} have demonstrated that the peaks of high IRD coincide with periods of high productivity of several species of radiolarians, and, indeed, our cores also have high accumulation rates of radiolarians which correlate with the high IRD and the melt-water events. Icebergs. due to their large size both above and below sea level, create small 'island effects' while drifting under the mixed influence of wind and currents. Reaching the area of high winds and rough seas (45-50° S), they will contribute to the vertical mixing, and hence increase the primary productivity. Neshyba41 has pointed out the importance of the iceberg-induced upwellings in the Weddell Sea. On the other hand, productivity is much smaller under a semi-permanent sea-ice cover⁸. It is therefore probable that sedimentation rate (both detrital and biogenic) was significantly higher during the melt-water events than it was between them. A duration of 1 kyr for each melt-water event, separated by 5 kyr of re-equilibration of the ice profile, is compatible both with the observed isotopic effects and with the present rate of ice accumulation. If similar phenomena were occurring at other places around Antarctica (especially east of the Ross Sea), each of the events would have had to be proportionately shorter to keep within the hypothetical constraint of a constant mean ice accumulation rate of 2,000 km³ yr⁻¹.

We therefore propose that the isotopic anomalies we observe record a succession of pulse-like surge events. Denton and Hughes³⁷ have stressed the importance for marine-based ice sheets of the removal of material by ice streams ('downdraw'). This mechanism feeds most of the present ice shelves in Antarctica. A large extension of the peripheral floating ice shelf around

Antarctica during the last glacial could have dramatically increased the volume of ice eroded by downdraw around the margins of the Antarctic ice sheet. Such a system would be semi-oscillatory, as ice streams would remove ice much more quickly than it could be replenished from the main body of the ice sheet. Within a few hundred years, all of the ice available at the head of the ice shelf would be removed, thus draining the coastal glaciers and ice streams. They will be reactivated only after a sufficient part of the ice sheet becomes once again marine-based. Similar models, with changes of smaller amplitude, have been discussed with respect to the present evolution of western Antarctica^{42,43}.

Denton and Hughes³⁷ have also stressed the teleconnections between Northern and Southern Hemisphere marine-based ice sheets. Their floating periphery is very sensitive to destabilization by sea-level changes. Moreover, each of the isotopic anomalies would represent an increase of several metres in global sea level, at the time when the boreal ice sheet was near its maximum extension. This may have helped to destabilize the marine-based ice sheets of the Northern Hemisphere, thus providing the amount of melting necessary to explain the high sea-level stands known around 25-30 kyr BP⁴⁴. A precise mapping of the net surface-water isotopic composition over the different oceans during the 17-30 kyr BP period, using a methodology similar to that presented here, should help to solve that problem.

Conclusions

Our results give new insight into the dynamics of the Antarctic ice sheet during the last glacial period. It is generally accepted that the Antarctic ice sheet had characteristics similar to those seen today³⁸, with a lower accumulation rate³⁴ and a surface temperature which responded in phase with global sea-level changes^{33,34}. We have demonstrated that the interactions between sea level, sea surface temperature around Antarctica, and the erosion rate of the Antarctic ice sheet may be more complicated. There is a definite indication that the Southern Ocean led by 2 kyr the North Atlantic warming and Northern Hemisphere deglaciation. A more important result of our study is that there have been several periods during the last glacial of large isotopic anomalies in the surface waters of the Antarctic polar front, particularly between 35 and 17 kyr BP. These anomalies are due to a large input of melt water during periods when the periphery of the Antarctic ice sheet was rapidly eroded. We propose that these events occurred during maximum extension of the marine-based ice sheets, and were due to the rapid erosion of the periphery of the Antarctic ice sheet by ice streams, flowing towards the ice shelves. When most of the ice available for feeding the coastal ice streams had been eroded, the ice shelves were destroyed, and iceberg calving decreased dramatically, until a new equilibrium ice-sheet profile was attained.

Generation of single-stranded T-DNA molecules during the initial stages of T-DNA transfer from Agrobacterium tumefaciens to plant cells

Scott E. Stachel', Benedikt Timmerman & Patricia Zambryski'

Laboratorium voor Genetica, Rijksuniversiteit Gent, B-9000 Gent, Belgium

Activation of the T-DNA transfer process of Agrobacterium by the plant signal molecule acetosyringone generates a single-stranded, unipolar, linear T-DNA molecule (T-strand)—a potential conjugative intermediate in the transfer of the T-DNA to plant cells. Acetosyringone induction also leads to S_1 nuclease-sensitive sites at the Ti plasmid T-DNA borders, and other molecular changes associated with the Ti plasmid T-DNA sequences, which may correspond to specific steps of T-strand synthesis.

DURING the genetic transformation of plant cells by the soil pathogen Agrobacterium tumefaciens (reviewed in ref. 1), a specific segment of DNA, the T-DNA, is recognized in and mobilized from the large (>200 kilobase pairs; kbp) Ti plasmid of the bacterium, transferred across the cell walls of the bacterium and plant cell, and integrated as an unaltered fragment into the plant nuclear genome. Analysis of the transfer process has focused on what defines the T-DNA; the genetic requirements for transfer other than the T-DNA; and the mechanism of transfer.

In the Ti plasmid the T-DNA is bounded by essentially identical 25-base pair (bp) direct repeats²⁻⁵. These sequences define the T-DNA, for any DNA, and only DNA, located between T-DNA borders is efficiently transferred and integrated⁶⁻⁹. The T-DNA transfer process is directed by the products of the Ti plasmid virulence (vir) and chromosomal virulence (chv) loci (reviewed in refs 10, 11). Whereas chv

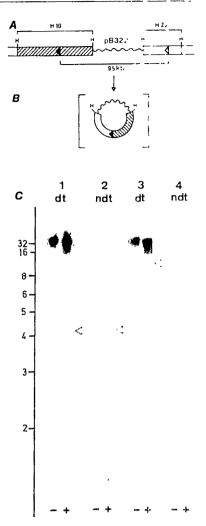

* Present address: Institute of Cancer Research and Howard Hughes Medical Institute, College of Physicians and Surgeons, Colombia University, New York 10032, USA (S.E.S.); Division of Molecular Plant Biology, Hilgard Hall, University of California, Berkeley, California 94720, USA (P.Z.).

expression is constitutive, vir expression is tightly regulated 12,13, and its activation initiates the transfer process. This activation is mediated by specific phenolic compounds present in the exudates of wounded and actively metabolizing plant cells. One such compound is dimethoxyphenol)¹⁴. acetosyringone (AS; 4-acetyl-2,6-

Genetic analyses of the 25-bp sequences have indicated that they are polar in function^{15,16}. While deletion of the left border repeat has no significant effect on pathogenicity¹⁷, deletion of the right repeat totally abolishes it^{15,16,18}. Furthermore, when the orientation of the right border is reversed with regard to its natural orientation on the Ti plasmid, the efficient transfer and/or integration of the T-DNA sequences is greatly attenuated. These results indicate that T-DNA transfer may occur in a rightward to leftward fashion, determined by the orientation of the 25-bp border repeats, and suggest that transfer might be via a conjugative mechanism¹⁵.

Here we use hybridization techniques to directly identify and characterize novel structures associated with the T-DNA and its border sequences in Agrobacterium following induction of vir gene expression with AS. A variation of the Southern blotting transfer procedure is used to distinguish between single-stranded (ss) and double-stranded (ds) DNA molecules present in total Fig. 1 Hybridization analysis of total DNA prepared from AS-induced Agrobacterium. B, Structure of the 9.5-kbp ds T-DNA circle molecule isolated after transformation of E. coli with undigested total DNA from AS-induced pGV3850 Agrobacteria. C, Southern blot hybridization analyses of Agrobacterium DNA. Total DNA prepared from ininduced (-) and AS-induced (+) 3850 agrobacteria was analysed by hybridization against nick-translated ³²P-labelled pBR322 probe. Lane 1, denatured transfer (dt) of untreated DNA; lane 2, non-denatured transfer (ndt) of untreated DNA; lane 3, denatured transfer of total DNA digested with S₁ nuclease; lane 4, non-denatured transfer of S₁-treated DNA. Scaling on left is in kbp. Arrows indicate novel signals observed in the AS-induced lanes. Note that all of these novel signals are also observed, albeit at a lower level, with DNA prepared from Agrobacterium co-cultivated with Nicotiana tabacum protoplast cells (data not shown).

Methods. An overnight culture of 3850 Agrobacteria grown in YEB liquid medium was resuspended in MSSP medium¹⁴ at $0.05 A_{600}$ units ml⁻¹ and grown at $28 \,^{\circ}$ C with high aeration. After 5 h of preincubation growth, acetosyringone (Janssen) was added to half of the MSSP culture at 100 µM, a concentration that is non-limiting for induction of the Ti-plasmid vir genes¹⁴. The uninduced and AS-induced cultures were grown for another 12-18 h and a parallel culture of the virB:: lac strain A348(pSM30) (refs 10, 14) was used to monitor vir induction; under these conditions the cultures undergo two to three doublings, and >100-fold increases in β -galactosidase activity are observed in A348(pSM30). The bacteria were collected by centrifugation and total DNA prepared as described previously³³. Briefly, the pellet from 5 ml of cells is lysed in 200 µl TE (50 mM Tris, 20 mM Na₂-EDTA, pH 8.0), 100 µl 5% sodium sarkosyl and 100 µl pronase (10 mg ml⁻¹) for 45 min at 37 °C. The lysate is then vortexed for 15 s (light-shear), extracted twice with phenol and twice with chloroform, and the DNA recovered by EtOH precipitation. E. coli was transformed with uninduced and AS-induced DNA as described previously¹⁹, and the AS-induced preparation was determined to give transformants carrying the ds T-DNA circle molecule diagrammed in B. Aliquots (1 µg) of total Agrobacterium DNA (either untreated or S1-digested) were then electrophoresed in 0.9% TBE agarose gels containing 0.5 µg ml⁻¹ EtBr, transferred to nitrocellulose in 10×SSC, and analysed by Southern blot filter hybridization. Two different transfer condtions have been used, denatured and non-denatured. For denatured transfer, the agarose gel is soaked in denaturing solution for 60 min followed by neutralizing solution for 60 min before capillary blotting. For non-denatured transfer, the gel is soaked in H₂O for 10 min, then 10×SSC for 10 min, before blotting. For the S₁ nuclease digestions, 1 μg total DNA in 200 μl S₁ digestion buffer was incubated with 50 U S₁ nuclease (Boehringer Mannheim) for 30 min at 20 °C. The reaction is terminated by adding 20 µl 10×S₁ termination buffer, followed by phenol extraction and EtOH precipitation. Unless otherwise specified, all buffers and conditions used here and in Figs 2-5 are according to Maniatis et al.34.

DNA prepared from these cells. Evidence is presented for (1) free ss T-DNA molecules (T-strands) whose polarity corresponds to that of the T-DNA borders; (2) ss endonucleases ensitive structures associated with the Ti plasmid T-DNA borders (S₁ border sites); and (3) molecular alterations associated with the internal sequences of the Ti plasmid T-region (T-region structures). We discuss the potential role of each of these AS-induced T-DNA homologous molecules in the transfer of the T-DNA to the plant cell.

Free T-DNAs in AS-induced cells

For these studies we used Agrobacterium carrying Ti plasmid pGV3850 (ref. 6). pGV3850 has been derived from the nopaline C58 Ti plasmid, and the structure of its minimal T-DNA region is shown in Fig. 1A. Strain 3850 has been used previously to isolate and identify a 9.5 kbp ds T-DNA circle molecule (Fig. 1B) following transformation of Escherichia coli with total DNA prepared from plant¹⁹ or AS-induced Agrobacteria¹⁴; this T-DNA circle has been proposed as a candidate for the T-DNA molecule that is transferred to the plant cell. Our initial experiments aimed to identify the presence of this molecule directly in Agrobacterium.

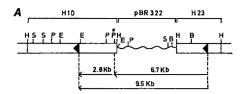

Total DNA was prepared from AS-induced cells and found to produce ds T-DNA circles in *E. coli*; this AS-induced DNA, along with total DNA prepared from uninduced cells, was fractionated by agarose gel electrophoresis and transferred to a nitrocellulose filter following gel denaturation (normal Southern transfer procedure, see below). Two T-DNA homologous signals are observed in Fig. 1*C*, lane 1. Since the DNA is undigested, the upper signal represents Ti-linked T-DNA sequences, while

the lower signal represents free T-DNA sequences. This novel signal is specific to the AS-induced DNA, and thus corresponds to a Ti-independent T-DNA molecule whose synthesis is the result of the AS-induced activation of the pGV3850 vir loci.

The free T-DNA signal does not migrate as a 9.5-kbp ds DNA molecule (supercoiled, relaxed-circular or linear), but instead migrates at a size corresponding to a ds linear molecule of 4.4 kbp. Thus, by hybridization we find no evidence for ds T-DNA circles in AS-induced bacteria. This result is not totally unexpected because the frequency of recovery of these molecules in E. coli is low. We obtain on average 50 ds circle transformants per µg AS-induced DNA (at a transformation efficiency of 10 transformants per µg supercoiled pBR322 plasmid DNA). Since 1 μg of total Agrobacterium DNA contains ~1.7 ng of pGV3850 T-DNA¹⁹, at most only one in every 100 AS-induced cells harbours a ds T-DNA circle. That these molecules are not detected by hybridization indicates that the transformation results are representative of their actual concentration in the AS-induced DNA. We discuss below a model for how ds circle molecules might be generated at a low frequency as a result of AS induction (Fig. 6).

Free T-DNAs are single stranded

Since the size of the AS-induced free T-DNA molecule is about half that of the T-region of pGV3850 (Fig. 1A), it may be a single-strand copy of the pGV3850 T-DNA. The following experiments demonstrate that the free T-DNA molecule has properties characteristic of ss DNA. Evidence is also given for other novel T-DNA-homologous molecules present in the AS-induced bacteria; in contrast to the free T-DNA, these structures

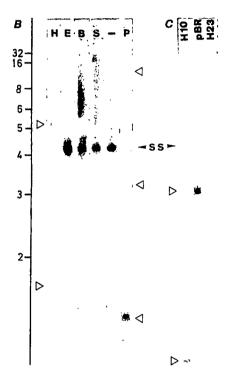

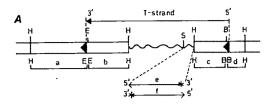

Fig. 2 Restriction endonuclease treatment of AS-induced DNA. A, Restriction map of the T-DNA region of pGV3850. Black arrows, T-DNA border sequences; the 9.5-kb arrow designates the ss T-DNA molecule, and the 2.8-kb and 6.7-kb arrows correspond to the ss fragments that would be produced by PstI cleavage of the ss T-DNA molecule at the PstI* site. B, Aliquots (1 µg) of ASinduced DNA were digested to completion with five restriction endonucleases, fractionated on 0.9% agarose, transferred under non-denaturing conditions to nitrocellulose, and analysed by hybridization against HindIII fragment 10/pBR322 probe. H, HindIII; E. EcoRI; B. BamHI; S. SalI; P. PstI; -, undigested; ss, free T-DNA molecule; open arrows, unexpected fragments produced by HindIII or PstI digestion of the AS-induced DNA. C, Three equivalent non-denatured transfers of PstI-digested ASinduced DNA were hybridized against HindIII fragment 10 probe (H10); pBR322 probe (pBR); and HindIII fragment 23 probe (H23). Scaling is different from that in B, such that the signals marked with triangles correspond to ss DNA molecules of ~6.6 and 2.8 kb, respectively. Note that different preparations of ASinduced DNA were used in the experiments of B and C. The \sim 9.2-kbp signal observed in the PstI digest in B is not observed in C; this difference may reflect the detection of different levels of AS-induced events in the two preparations.

are still linked to the Ti plasmid, as they are only detected after enzymatic digestion.

Transfer assay for ss T-DNAs. DNA binds to nitrocellulose only if it is single-stranded²⁰ or associated with protein²¹. In the Southern blotting technique, ds DNA fragments fractionated in an agarose gel must be denatured before being transferred to nitrocellulose²⁰. Thus, ss (and protein-associated) DNA molecules can be easily distinguished from ds molecules by comparing their transfer to nitrocellulose from agarose gels treated with or without NaOH before transfer. Figure 1C, lanes 1 and 2, show the denatured and non-denatured transfers of

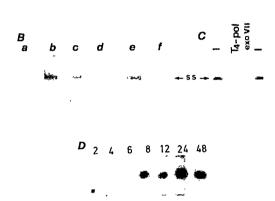

Fig. 3 Molecular characterization of ss T-DNA molecules. A, Six probes used to analyse the sequence content and strandedness of the ss T-DNA molecule. B, BcII; E, EcoRI; H, HindIII. The EcoRI site of probes a and b falls 55 bases inside the left T-DNA border, and the BcII site of probes c and d falls 42 bases inside the right border.

Methods. Fragments a, b, c and d were gel-purified twice and labelled by nick translation. Probes e and f are 3'-end-labelled probes where the position of the label is marked by an asterisk, and correspond to the upper and lower strands of the pGV3850 T-DNA, respectively. For probe e, pBR322 was digested with HindIII, 3'-end-labelled at the HindIII site by Klenow fill-in, recut with SalI, and the resultant 622-bp HindIII/SalI fragment was gel-purified. For probe f, the order of the restriction digests was reversed to give a 622-bp Sall/HindIII fragment, 3'-end-labelled at the SalI site. The polarity of the ss T-DNA molecule, or T-strand, is shown at the top of the figure. B, Sequence content and strandedness of the ss T-DNA. Six equivalent strips of a non-denatured transfer of undigested AS-induced DNA hybridized against the six probes shown in A. ss, Single-stranded T-DNA signal. C, Exonuclease sensitivity of the ss T-DNA. The non-denatured transfer of untreated (-), T4 polymerase-digested (T4-pol), and exonuclease VII-digested (ExoVII) AS-induced DNA was hybridized against nick-translated pBR322 probe. For exonuclease digestion, 1-µg aliquots of AS-induced DNA were incubated with 2.5 U T4 polymerase (Anglian Biotechnology Ltd) or 1.1 U exonuclease VII (Gibco-BRL), respectively, for 30 min at 37 °C. Each reaction was carried out in 15 µl in the enzyme buffer recommended by the manufacturer. Note that under identical conditions these treatments have no effect on M13 ss circular phage DNA; also, the ss T-DNA is fully degraded after 90 min digestion with T4 polymerase (data not shown). D, Kinetics of synthesis of the ss T-DNA molecule. A 50-ml culture of pGV3850 Agrobacteria pregrown for 5 h was then induced with AS at 100 μM. At 2, 4, 6, 8, 12, 24 and 48 h after the start of induction, 5-ml aliquots were removed, frozen at -70 °C, and total DNA was then prepared. These DNA samples were fractionated on agarose and transferred to nitrocellulose without gel denaturation, and the amount of ss T-DNA molecules present in the AS-induced cells for each time point was assessed by hybridization against nick-translated pBR322 probe. Note that by EtBR staining the amount of DNA in the 24-h lane was about double that for the other lanes.

uninduced and AS-induced total DNA. Of the two T-DNA-homologous signals present in the AS-induced DNA sample, only the lower signal, which represents the free T-DNA molecule, transfers without gel denaturation (Fig. 1C, lane 2). This free T-DNA must be ss DNA because the AS-induced total DNA has been fully deproteinated during its preparation (Fig. 1

legend) and RNase digestion of the DNA before hybridization analysis does not affect the ss signal (data not shown).

Nuclease sensitivity of ss T-DNAs. S_1 nuclease is a ss-specific endonuclease²². In Fig. 1C, the denatured (lane 3) and non-denatured (lane 4) transfers of S_1 nuclease-digested samples of uninduced and AS-induced total DNA demonstrate that the free T-DNA molecule is fully degraded by S_1 nuclease. Interestingly, S_1 treatment also appears to release the T-region from the AS-induced T1 plasmid. A novel T-DNA homologous signal is observed in the S_1 -treated AS-induced sample in the denatured transfer (Fig. 1C, lane 3), and this signal corresponds to a ds molecule, which migrates as a linear fragment of 9.5 kbp, the precise size of the pGV3850 T-DNA from its left to right T-DNA borders (Fig. 1A). Thus, AS induction also results in a Ti plasmid whose T-DNA borders are sensitive to cleavage by S_1 nuclease (see Figs 4 and 5).

The activity of type II restriction endonucleases is limited primarily to duplex DNA. Aliquots of AS-induced DNA were digested to completion with BamHI, EcoRI, HindIII, PstI and SalI (each of these enzymes cleaves within the T-DNA region of pGV3850; Fig. 2A), and hybridized to the HindIII fragment 10/pBR probe following non-denatured transfer (Fig. 2B). Because the ss signal is present in all the digests (except for PstI), the free T-DNA is generally resistant to restriction digestion.

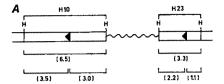

The HindIII and PstI results are more complex. The ss signal is weak in the HindIII lane and absent in the PstI lane; also, several novel signals are observed in these lanes. Several restriction enzymes have been shown to restrict ss DNA²³, and the sensitivity of the free T-DNA to HindIII and PstI may be an example of this effect. Interestingly, fragments both smaller and larger than the ss T-DNA molecule are produced by HindIII and PstI digestion (Fig. 2B). While the smaller fragments can be cleavage products of the ss T-DNA, the larger fragments must be derived from a large molecule, presumably the AS-induced Ti plasmid. Thus, AS induction also results in a Ti plasmid molecule whose T-region carries ss sequences (see Fig. 5).

Characterization of ss T-DNAs

ss T-DNAs are full-length and unipolar. Six identical strips of a non-denatured transfer of undigested AS-induced DNA were hybridized separately with the six probes labelled a to f in Fig. 3A. Probes a and d correspond to pGV3850 sequences just outside the left and right T-DNA border repeats; probes b and c correspond to T-region sequences just within these repeats; and probes e and f correspond to the upper and lower strands of the pGV3850 T-DNA region, respectively. Figure 3b shows that the ss T-DNA molecule hybridizes only to probes b, c and e. Thus, it is composed only of sequences located internal to the T-DNA borders, and which correspond to the lower strand of the pGV3850 T-region. We designate this unipolar ss T-DNA molecule as the T-strand.

T-strands are linear. The T-strand is sensitive to both exonuclease VII $(3' \rightarrow 5')$ and $5' \rightarrow 3'$ activities specific for ss DNA²⁴ and T4 polymerase $(3' \rightarrow 5')$ exonuclease that accepts both ss and ds DNA as substrate (Fig. 3C). Thus, the T-strand, as isolated, must be a linear ss DNA molecule whose 3' terminus (and perhaps also 5' terminus) is available to exonuclease digestion.

The PstI cleavage products of the T-strand indicate that its 5' and 3' ends map to the right and left T-DNA borders, respectively. Two fragments of ~3.3 and 1.4 kbp (~ss lengths 6.7 and 2.8 kbp) are detected. The 6.6-kbp fragment is homologous to pBR322 and HindIII fragment 23, while the 2.8-kbp fragment is homologous only to HindIIII fragment 10 (Fig. 2C). Cleavage of a circular T-strand molecule at any (or all) of its three PstI sites would yield fragments of different sizes and sequence content from those observed. The simplest explanation for the results of Fig. 2C is that the T-strand is a linear ss molecule, cleaved by PstI principally at its middle PstI site (just within

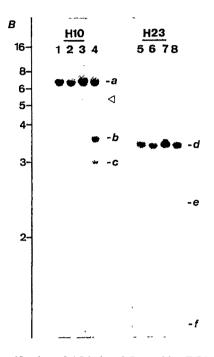

Fig. 4 Identification of AS-induced S₁-sensitive T-DNA border structures. A. HindIII fragments produced by ds cleavages of the pGV3850 T-DNA borders. Fragments b and c result from cleavage of the left border repeat carried by HindIII fragment 10 (a). Fragments e and f result from cleavage of the right T-DNA border carried by HindIII fragment 23 (d). Fragment sizes are in kbp. Black arrows, T-DNA border sequences; H, HindIII. B, Uninduced and AS-induced DNA was digested with HindIII, and half of each sample was treated further with S1 nuclease. The four samples were analysed on two denatured transfers hybridized against nick-translated HindIII fragment 10 (lanes 1-4) or HindIII fragment 23 probe (lanes 5-8). Lanes 1, 5, uninduced DNA; lanes 2, 6, uninduced DNA plus S₁ treatment; lanes 3, 7, AS-induced DNA; lanes 4, 8, AS-induced DNA plus S₁ treatment. a-f refer to the fragments shown in A. The open arrow indicates a novel S_1 -sensitive fragment of ~ 5.2 kbp. Scaling is in kbp. Note that the low level of the border cleavage fragments (b, c, e, f) seen in the absence of S₁ treatment (lane 3, and lane 7 after long exposure) may reflect mechanical breakage of the AS-induced S₁-sensitive border structures during sample preparation.

the right end of its *HindIII* fragment 10 sequences), to produce a 6.7-kbp 5' and a 2.8-kbp 3' fragment.

T-strand synthesis is limited. Using a probe homologus to both strands of the T-DNA, the intensity of the T-strand signal is ~5-10-fold less than the Ti-plasmid T-region signal (Fig. 1C, lane 1; also Fig. 5). As the T-strand corresponds to one strand of the T-region, and the copy number of the Ti plasmid is about two (and assuming no specific loss of T-strands during DNA preparation), we estimate that on average each AS-induced cell carries 0.4-0.8 T-strand molecules. As T-DNA homologous molecules are not found in the culture medium (data not shown), this low copy number is probably not due to export of the T-strand. Figure 3D demonstrates that the relative amount of T-strands begins to plateau within 8 h after the start of AS induction, and shows only a doubling during an additional 40 hours of induction. Thus, T-strand synthesis is a limited process.

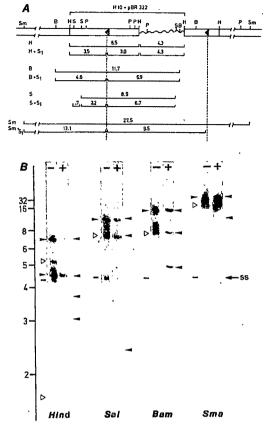

Fig. 5 Hybridization analysis of T-region intermediate structures. A, Restriction map of the left portion of the pGV3850 T-DNA region and border cleavage fragments predicted to arise after S1 treatment of AS-induced DNA. Sizes are given in kbp. B, BamHI; H. HindIII; P, Pst1; S, SalI; Sm, SmaI; S1, S1 nuclease. The black arrows and dotted lines indicate the positions of the T-DNA borders. B, Denatured transfers of HindIII, BamHI, SalI and Small digests of AS-induced DNA treated (+) and untreated (-) with S₁ nuclease were hybridized against nick-translated HindIII fragment 10/pBR322 probe (A). Scaling on left is in kbp. The single-stranded T-strand is indicated by ss and the bar adjacent to the digests. Solid arrows indicate the expected fragments before and after S₁ treatment and correspond in size to the fragments shown in A. The open arrows indicate unexpected AS-induced fragments which correspond to novel T-DNA homologous structures linked to pGV3850. Note that other unexpected signals are observed when the filter is reprobed with HindIII fragment 23 sequences, and that all of the unexpected fragments are specific to AS-induced DNA and have been observed with DNA prepared from at least two independent AS-induced bacterial cultures (data not shown).

AS-induced alterations of the Ti plasmid

Since the T-strand must be produced from the Ti-plasmid T-region, several molecular reactions involving these sequences should occur in bacterial cells that are actively carrying out different steps of T-strand synthesis, or other early steps of T-DNA transfer. To gain insight into these reactions, the novel T-DNA homologous hybridization signals that result from fragmentation of the AS-induced Ti plasmid with restriction enzymes and S₁ nuclease are characterized below. These data provide evidence for specific reactions associated with the Ti-plasmid T-DNA border repeats and with the internal sequences of the T-region.

 S_1 -sensitive T-DNA border sites. Figure 4 demonstrates that AS induction leads to the generation of Ti-plasmid T-DNA border structures which are sensitive to cleavage by S_1 nuclease. Uninduced and AS-induced DNA was restricted with *HindIII*, half of each sample was treated further with S_1 nuclease, and the

fragments homologous to the left and right border regions of pGV3850 were detected by hybridization. The AS-induced DNA lanes contain novel signals whose sizes correspond exactly to the fragments that would be produced by ds cleavages at the left and right T-DNA border sequences of pGV3850 (Fig. 4A), and the intensities of these signals are greatly increased by S_1 digestion of the DNA. We designate these S_1 -sensitive structures S_1 border sites.

The relative intensities of the signals which correspond to the S_1 border cleavage fragments show that ~30% of the left T-DNA borders and ~10% of the right T-DNA borders of the ASinduced Ti plasmid population are S₁-sensitive. Thus, the generation of S, border sites is a frequent event. Furthermore, since a 9.5-kbp ds T-DNA fragment is produced by S, digestion of AS-induced DNA that is unrestricted (Fig. 1C, lane 3), or restricted with SmaI (which does not cleave within the pGV3850 T-region (Fig. 5)), S₁ border sites can simultaneosly occur at both the right and left border repeats on a single Ti plasmid. We note that incubation of the uncut AS-induced DNA at 65 °C does not result in the release of the 9.5-kbp T-DNA fragment from the AS-induced Ti plasmid (data not shown); that is, the S₁ border site does not correspond to a ds staggered cleavage of the T-DNA border sequence. Other experiments have shown that the S₁-sensitive structure corresponds to an AS-induced ss endonucleolytic cleavage in the bottom strand of the 25-bp border sequence (K. Wang and M. Van Montagu, in preparation); S₁ is known to cleave opposite such structures^{26,27}.

Other AS-induced T-region structures. Figure 5 demonstrates that other novel Ti-plasmid-linked T-region structures are also present in the AS-induced cell population. Three different classes of T-DNA-homologous signals are observed when AS-induced DNA is digested with various restriction enzymes and S_1 nuclease (Fig. 5B): those that correspond to the ss T-DNA molecule (black bars, $-S_1$ lanes); those that correspond to the predicted border cleavage fragments (Fig. 5A) produced by S_1 digestion of the AS-induced S_1 border sites (solid arrows, $+S_1$ lanes); and those that correspond to novel unexpected fragments (open triangles) derived from pGV3850 Ti plasmids whose internal T-region sequences have been altered as a result of AS induction.

For example, the 5.2-kbp fragment present in the -S₁ HindIII sample (Fig. 5B; also Figs 2B and 4B) is S_1 -sensitive, binds to nitrocellulose, specifically hybridizes to HindIII fragment 10 (and not to pBR322 or HindIII fragment 23; data not shown), and is ~ 1.3 kbp smaller than HindIII fragment 10 (Fig. 5A). Thus, this novel HindIII fragment must be partially singlestranded and derived from an AS-induced Ti plasmid whose T-region is partially single-stranded or associated with ss T-DNA sequences, as in a D-loop structure. More perplexing fragments are also detected: the ~15-kbp S₁-insensitive SmaI signal corresponds to a ds DNA fragment which is ~12 kbp smaller than the Smal fragment that covers the T-region of the uninduced Ti plasmid; also, in the -S₁ BamHI and SalI lanes, signals are observed whose sizes correspond to the S₁ cleavage fragments of these digests (Fig. 5A) which are internal, but not external, to the left T-DNA border. While the present data do not allow the precise identification of the T-region structure(s) to which these unexpected fragments correspond, they illustrate the complexity of the molecular reactions associated with the Ti-plasmid T-DNA sequences which occur in AS-induced Agrobacteria.

Discussion

Agrobacterium tumefaciens transfers its Ti-plasmid T-DNA to plant cells, and this process is activated by the induction of the Ti-plasmid virulence genes with the plant phenolic compound AS. We show that AS induction results in the generation of several novel T-DNA homologous molecules in Agrobacterium: a linear ss molecule, the T-strand, which corresponds to the lower strand of the Ti-plasmid T-region; and Ti-plasmid molecules whose T-DNA border repeats are sensitive to cleavage

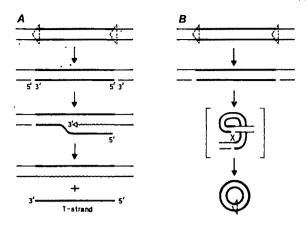

Fig. 6 Proposed reactions associated with the Ti-plasmid Tregion in AS-induced cells. A, Model for the generation of the T-strand; B, model for the generation of a ds T-DNA circle molecule. Thick lines represent T-region sequences, thin lines represent adjoining Ti-plasmid sequences external to the 25-bp T-DNA border repeats, indicated by the dashed triangles, as breaks in the bottom strand of the border repeats correspond to Siborder sites, and the wavy line corresponds to a newly synthesized bottom strand of the T-region. This model implies that ss molecules are not generated leftward of the left T-DNA border; while we have not observed such molecules, they might not have been detected if they are heterogeneous in length.

by S₁ nuclease (S₁ border sites), and whose internal sequences have been altered (T-region structures). The specific properties of these AS-induced molecules allows the formulation of mechanistic models for the generation of the T-strand, and for its potential transfer to the plant cell.

Figure 6A presents a model for the generation of the T-strand molecule. First, ss endonucleolytic cleavages occur within the left and right T-DNA border sequences on the Ti plasmid. These cleavages correspond to S₁ border sites and provide free 3' OH groups from which DNA synthesis can be primed. Second, using the top strand of the T-region as template, DNA synthesis initiates at the right border cleavage site, and proceeds unidirectionally across the T-region. This synthesis displaces the bottom strand of the T-region and produces a transitory triple-stranded structure which may correspond to one of the AS-induced Tregion structures that we have detected. Third, DNA synthesis terminates when it encounters the left border cleavage site, and the displaced bottom strand is released from the Ti plasmid, as the free T-strand ss molecule. Alternatively, a $5' \rightarrow 3'$ helicase activity unwinds the T-region of the nicked Ti plasmid to free the T-strand molecule and produce a Ti plasmid whose T-region is momentarily ss prior to replacement strand synthesis. Since we observe at most one T-strand molecule per AS-induced cell. T-strand production must be tightly regulated.

The sequences internal to the T-DNA of the wild-type Ti plasmid encode genes whose expression in the transformed plant cell result in the tumorous phenotype, crown gall¹, and when the orientation of the right border on the Ti plasmid is flipped (by in vitro manipulation), phenotypically transformed plant cells are not obtained 15,16. The model of Fig. 6A explains this functional polarity of the right T-DNA border; that is, the T-strand corresponds to the bottom strand of the T-region and must be generated in a right-to-left (5' to 3') direction. Thus, if the orientation of the right border is reversed in the Ti plasmid, ss molecules will be generated away from (rightward of) the T-DNA tumour genes. This model may also explain how the ds T-DNA circle molecules, recovered in E. coli transformed with AS-induced DNA, are generated at a low frequency in response to AS induction. Since nicked DNA stimulates recombination events²⁸, the S₁ border sites could promote pairing and recombination between the T-DNA border repeats of the AS-induced Ti plasmid (Fig. 6B).

Assuming that the T-strand is the transfer intermediate, we can speculate on the mechanism of its transfer. This mechanism might share features with known bacterial processes which mediate the transfer of specific DNA molecules between bacteria, such as phage infection or conjugation. An important distinction between these two processes is that only phage infection involves the synthesis of many copies of the molecule destined for transfer. Since the T-strand is present at about one copy per ASinduced cell, it is unlikely that it is transferred to the plant cell as an infectious phage particle.

In bacterial conjugation, one strand of a ds donor molecule is transferred as a linear ss molecule from the donor to recipient cell²⁹. This process is initiated by nicking one strand of the donor molecule at a specific site (designated oriT, origin of transfer)³⁰, and the strand destined for transfer is unwound in a $5' \rightarrow 3'$ direction. Concomitant to unwinding, the unwound strand is mobilized to the recipient cell, and this transfer is accompanied by DNA synthesis on the donor molecule to replace the mobilized strand. The T-DNA homologous molecules that we have described correspond to the structures which would be predicted to occur if T-DNA transfer occurs through a conjugative mechanism. The S₁ border sites are analogous to nicked oriT sites, the T-strand is analogous to the linear ss DNA molecule transferred during bacterial conjugation, and the internal T-region structures are analogous to the replacement strand synthesis intermediates of the donor molecule. Furthermore, bacterial conjugation requires direct contact between donor and recipient cells11, and the same requirement is observed for the T-DNA transfer process¹².

If the T-strand is transferred by conjugation to the plant cell. it is still not known how it ultimately finds its way into the plant cell nucleus and becomes integrated into the nuclear genome. While the deproteinized T-strand that we have described is a naked linear molecule, presumably it is transferred as a complex that carries proteins which in part mediate the post-transfer events. These proteins, as well as the proteins involved in the generation and transfer of the T-strand, are probably encoded by the plant-inducible Ti-plasmid vir loci10

We thank Marc Van Montagu for his encouragement and suggestions for the exonuclease studies, Kan Wang for helpful discussion, Jeff Schell for support, and Martine De Cock, Karel Spruyt and Albert Verstraete for preparation of this manuscript and figures. This work was supported by grants from the 'ASLK-Kankerfonds', the 'Fonds voor Geneeskundig Wetenschappelijk Onderzoek' (FGWO 3.001.82), and the Services of the Prime Minister (OOA 12.0561.84) (to Jeff Schell and Marc Van Montagu),

Note added in proof: The nondenatured transfer assay for singlestranded DNAs has also been recently described by Reile, H. T., Michel, B. and Ehrlich, S. D. Proc. natn Acad. Sci. U.S.A. 83, 2541-2545 (1986).

Binary pulsar with a very small mass function

R. J. Dewey*, C. M. Maguire†, L. A. Rawley†, G. H. Stokes† & J. H. Taylor†

* Center for Radiophysics and Space Research, Cornell University, Ithaca, New York, 14853, USA † Joseph Henry Laboratories and Physics Department, Princeton University, Princeton, New Jersey 08544, USA

Much of the interesting physics concerning neutron stars and their evolution depends for its experimental foundation on observations of the rotation rates of pulsars. To continue recent efforts of our group in this area 1-3, we began a series of pulse-arrival-time observations of ~70 pulsars in January 1985. Most of the pulsars in this study were discovered in the Princeton/NRAO pulsar survey of the preceding two years^{4,5}. Soon after we began these observations it became clear that PSR2303+46 was a binary pulsar2; it is now evident that PSR1831-00 is also a member of a binary system, the seventh such radio pulsar known. It moves in an orbit with a period of 1.81 days, a small eccentricity, and an unusually small mass function of 0.90012 M_{\odot} (where M_{\odot} is the mass of the Sun). With a period P = 0.521 s and period derivative $\dot{P} \leq 10^{-17}$ s s-1, PSR1831-00, like the other known binary pulsars, has a relatively weak magnetic field. We discuss the features of this system that provide clues to its evolutionary history and outline possible models for its formation.

Most of our observations were made with the 92-m transit telescope at Green Bank, West Virginia, at a frequency of 390 MHz. The data acquisition system has been described by Stokes et al.5. Briefly, a dual-channel parametric up-converter amplifies two orthogonal linear polarizations and provides a system noise temperature of 50 K at high galactic latitudes. In the direction of PSR1831-00 (galactic coordinates $l = 30.8^{\circ}$, b =3.7°) the system temperature is 180 K, equivalent to a flux density of ~150 Jy. In each polarization an 8-MHz pass-band is divided into 32 sub-channels, each 250 kHz wide; the signals are detected, summed in a de-disperser, and then integrated for two minutes in a signal averager synchronized to the apparent pulsar period. For each pulsar, the resulting profiles are cross-correlated with a standard profile for that pulsar. This procedure determines phase offsets which, when added to reference times near the centre of the integrations, yield effective pulse arrival

For PSR1831-00, one to ten arrival times were obtained in this way on each of 19 days in January, February, April, July and November 1985, and February 1986. The number of observations obtainable on a single day is limited by the small hour-angle range through which the 92-m telescope can track (~20 min at the celestial equator), and this in turn limits the accuracy with which one can measure a pulsar's apparent period on a given day. Neverthless, for virtually all non-binary pulsars it is possible to fit data obtained over two or three days to a single barycentric period and to count pulses unambiguously

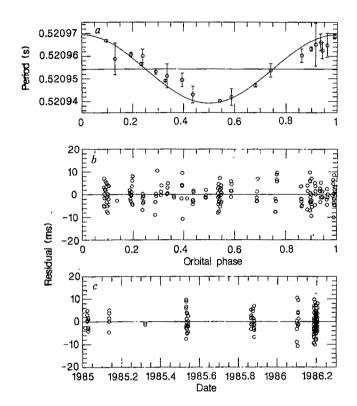

Fig. 1 Pulsar period as a function of orbital phase (a), and arrival-time residuals as function of both orbital phase (b) and date (c). The sinusoid superimposed on the measured periods in a corresponds to the orbital parameters listed in Table 1.

from day to day. The data for PSR1831-00 were not amenable to such treatment; it was rarely possible to fit data taken one or two days apart to a single period. However, the day-to-day period changes were small (a few parts in 10⁵) and only marginally significant, making the binary nature of this pulsar hard to recognize.

These difficulties were compounded by the weakness of the pulsar's signal (2-5 mJy) and its variability. We did not detect the pulsar in a number of our attempts to observe it, and there is some evidence that it has become weaker in the past year. The variability may be due to refractive interstellar scintillation. Our failures to detect the pulsar show no correlation with orbital phase, so there is no evidence that eclipses are involved.

Redoubled observational efforts in February 1986 showed that the data were consistent with a nearly circular orbit having a 1.81-day period and a maximum radial velocity of ±8.7 km s We were still not able, however, to connect pulsar phases unambiguously between observing days. Consequently, during March 1986 we observed PSR1831-00 at 430 MHz with the Arecibo 305-m telescope. The data acquisition scheme is described in ref. 6. The pulsar is close to the southern declination limit of the Arecibo antenna and can therefore be observed for only 50 min each day; however, the improvement in tracking time over that available at Green Bank allowed us to connect pulsar phases between observations made on 10, 12, 13, 14 and 16 March. An orbital solution obtained using the method described by Manchester and Taylor⁷ was good enough to allow unambiguous phase connection to all of the earlier Green Bank data. The resulting global solution for pulsar and orbital parameters is presented in Table 1, and the orbital velocity curve

Table 1 Parameters of the PSR1831-00 system						
Right ascension (1950.0)	$\alpha = 18 \text{ h } 31 \text{ min } 43.23 \pm 0.08 \text{ s}$					
Declination (1950.0)	$\delta = -00^{\circ} \ 13' \ 13.5 \pm 1.8''$					
Pulsar period	P = 0.5209543084(3)s					
Period derivative	$P = (0.2 \pm 1.6) \times 10^{-17} \text{ s s}^{-1}$					
Dispersion measure	$DM = 94 \pm 6 \text{ cm}^{-3} \text{ pc}$					
Projected semi-major axis	$a_1 \sin i = 0.7227 \pm 0.0010$ light s					
Eccentricity	e < 0.005					
Orbital period	$P_b = 156478.9 \pm 0.4 \text{ s}$					
Time of periastron	$T_0 = 2,446,460.3411 \pm 0.0011 \text{ JD}$					
Assumed longitude of periastron	$\omega = 0.0^{\circ}$					

and post-fit arrival-time residuals are shown in Fig. 1. We note that our measured period derivative, although effectively an upper limit, already places PSR1831-00 among the dozen pulsars with the smallest slow-down rates, as can be seen in Fig. 2. A small rate of spin-up is also consistent with our data—and would be most interesting if confirmed—but is not yet required. At present only an upper limit is available for the orbital eccentricity. If it is as small as the eccentricities of the PSRs 0655+64, 1855+09 and 1953+29, it will be impossible to measure because the ratio $(a_1 \sin i)/P$ for PSR1831-00 is so small. $(a_1 \text{ is the orbital semi-major axis; } i$ is the angle between the plane of the orbit and the plane of the sky.)

The orbital period and semi-major axis determine the mass function:

$$f(m_1, m_2) = \frac{(m_2 \sin i)^3}{(m_1 + m_2)^2} = \frac{4\pi^2}{G} \frac{(a_1 \sin i)^3}{P_b^2} = 0.000123 \ M_{\odot}$$

where m_1 and m_2 are the masses of the pulsar and companion, respectively. As shown in Fig. 3, this constraint implies a very small companion mass, $\sim 0.05-0.15~M_{\odot}$, unless cos *i* is implausibly close to 1.

As can be seen in Table 2, the 1831-00 system is similar in many respects to the other known binary pulsars. Like the other binaries, the pulsar has an unusually small spin-down rate and an unusually small inferred magnetic field, $B=3.2\times10^{19}\,(P\dot{P})^{1/2}<8\times10^{10}\,\mathrm{G}$. All seven binary pulsars lie between the 'spin-up line' and the 'death line'^{3,8} in the $P-\dot{P}$ diagram, as shown in Fig. 2. Taylor and Stinebring' note that the known binary pulsars and the millisecond pulsar 1937+21 show a correlation between magnetic field and distance |z| from the galactic plane, a pattern into which PSR1831-00 fits nicely (see Table 2). Although this relation may be partly due to selection effects—searches for millisecond pulsars (expected to have small magnetic fields) have tended to concentrate at low latitudes—it may also provide information about how binary

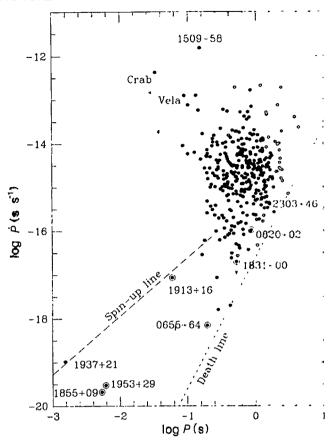

Fig. 2 Distribution of periods and period derivatives for 353 pulsars. The seven known binary pulsars, indicated by circles around the dots, have unusually small period derivatives and hence relatively weak magnetic fields.

and millisecond pulsars are formed, and may be related to the correlation between magnetic field and velocity first noted by Anderson and Lyne¹⁰. This correlation does not, however, follow simply from models of binary pulsar formation such as those outlined by van den Heuvel⁸.

What makes the 1831–00 system atypical, and its evolutionary history somewhat difficult to understand, is its relatively tight orbit (component separation $\sim 6~R_{\odot}$, where R_{\odot} is the radius of the Sun) and extremely small mass function. Models for the formation of binary pulsars⁸ suggest that during evolution a low-mass companion will spiral away from a neutron-star primary, leaving a final system with a wide orbit similar to those of PSRs 1953+29 and 0820+02. Nevertheless, a number of features of the evolution of the 1831–00 system may be inferred from its orbital parameters and the pulsar's period and spindown rate.

The pulsar's small magnetic field suggests that it is relatively old ($\ge 3 \times 10^7$ yr, assuming a magnetic field decay time of 10° yr and a magnetic field of 10^{12} G at birth¹¹). As the system presently

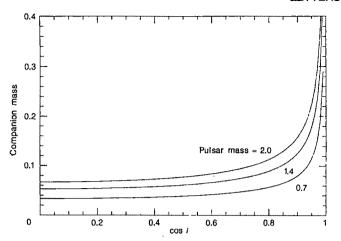

Fig. 3 Mass of the companion of PSR1831-00, plotted as a function of cos i and assuming three different values for the mass of the pulsar. All masses are in units of M_{\odot} .

lies ~200 pc above the galactic plane, such an age implies a velocity of ≤10 km s⁻¹, substantially smaller than that of the average pulsar. A shorter magnetic field decay time or smaller initial magnetic field would allow a larger velocity. The position of the pulsar in the $P-\dot{P}$ diagram (Fig. 3) allows, but does not require, that the pulsar has been spun up by accretion from its companion.

The system's circular orbit is compatible with the companion having undergone mass loss after the pulsar was created. If this is the case, the pulsar may have been formed by the accretioninduced collapse of a white dwarf, which would explain the system's low apparent velocity. However, it is also possible that no mass transfer has occurred since the formation of the neutron star in a supernova explosion, and that tidal forces have circularized the orbit. If the companion has a substantial convective envelope, such forces may be able to do this quite effectively¹².

For cos $i \le 0.95$ the companion mass is too small for the companion to be the white-dwarf or helium-core remnant of a star that has evolved off the main sequence in the age of the universe. If the companion is the remnant of an evolved star which underwent mass loss, that mass loss must have occurred before the end of the star's hydrogen burning, and before a sizeable compact core could develop.

This evidence points to two alternative evolutionary models, one involving mass transfer after (or during) the formation of the neutron star, and one in which no mass transfer has occurred. In both models the neutron star is formed from the primary of the original main-sequence system. In the former case, because the companion must have overflowed its Roche lobe before leaving the main sequence, the orbit after the collapse of the primary must have been quite small. This suggests that the progenitor system passed through a contact phase during the primary's evolution. During this phase the secondary may have accreted a significant amount of matter, but this is not required. Once the secondary overflowed its Roche lobe, the system may have appeared as a cataclysmic variable or low-mass X-ray binary and during this stage a white dwarf might be pushed over the Chandrasekhar limit. The compact primary's motion must have acted to eject the envelope of the secondary, a process which appears to be possible, given suitable conditions¹³. If the pulsar was formed by accretion-induced collapse, the most likely pre-neutron-star candidates are an O-Ne-Mg white dwarf whose progenitor was a fairly massive ($\geq 8 M_{\odot}$) star, or a very old CO white dwarf14

In the alternative model, the companion is a normal low-mass star which has evolved very little since the formation of the pulsar in a supernova explosion. In order for the system to have remained bound, the primary must have had a mass of \sim 3 M_{\odot} when it exploded, unless very limiting assumptions are made

about asymmetries in the supernova explosion. This again requires a contact phase during the evolution of the primary, in this case, one in which the companion accreted very little matter. The explosion of any helium star massive enough to have formed a neutron star would have induced a substantial (≥0.5) eccentricity in the system's orbit, so this model is viable only if tidal forces could have circularized the orbit within the lifetime of the pulsar.

We are grateful to T. H. Hankins, D. R. Stinebring and K. Turner for allowing us to use the Arecibo telescope during part of their scheduled time, and to J. M. Cordes and A. Wolszczan for help with some of the observations. We thank the staffs of the National Radio Astronomy Observatory and the National Astronomy and Ionosphere Center for assistance with the observations and NSF for financial support. R.J.D. thanks E. E. Salpeter for informative discussions on the evolution of low-mass stars.

New millisecond pulsar in a binary system

D. J. Segelstein, L. A. Rawley, D. R. Stinebring, A. S. Fruchter & J. H. Taylor

Joseph Henry Laboratories and Physics Department, Princeton University, Princeton, New Jersey 08544, USA

Recent observations^{1,2} at the Arecibo Observatory have resulted in the discovery of PSR1855+09, a pulsar with period P =5.362 ms, moving in a nearly circular orbit of period 12.3 days. The pulsar is only the third one known with P < 10 ms, and the sixth known radio pulsar in a binary system. (Discovery of a seventh binary pulsar is announced in an accompanying paper3.) Three of the seven binaries are among the fastest five of more than 400 pulsars—a fact that provides strong support for the conclusion that fast pulsars are 'recycled' neutron stars, spun up during a phase of mass accretion from an evolving companion star. The pulsar has a small dispersion measure (13.3 cm⁻³ pc), suggesting a distance of only ~350 pc. The proximity of this pulsar and its location within 25 pc of the galactic plane argue that millisecond pulsars form a significant fraction ($\sim 10\%$) of the pulsar population, leaving many detectable ones undiscovered^{4,5}. Its signal is strong enough to permit pulse-arrival-time measurements with single-day uncertainties of <3 \(\mu s\). Timing observations already suggest that PSR1855+09, like the 1.5-ms pulsar PSR1937+21, will prove to be a natural clock of extremely high stability⁶. The existence of a second pulsar with extremely small timing uncertainties will greatly aid the search for background gravitational waves using millisecond pulsars as detectors.

Observations leading to the discovery of PSR1855+09 were part of a survey specifically designed to detect fast pulsars¹. The Arecibo 305-m telescope was used at a frequency of 430 MHz, where a 30-m line feed provides a sensitivity of up to 19 K Jy⁻¹

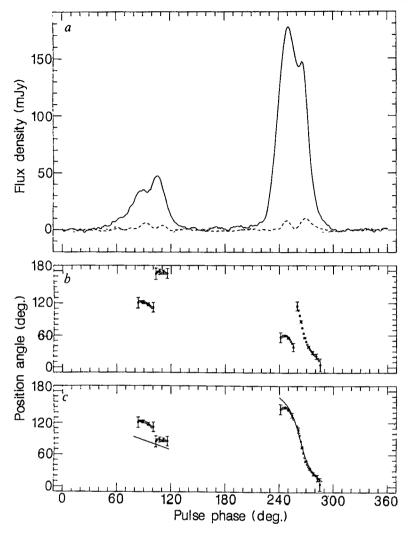

Fig. 1 Total intensity and polarization profiles for PSR1855+09. a. Total intensity (solid line), linear polarization (dashed line) and circular polarization (dotted line) for a synchronous average of ~560,000 pulses. There are 256 samples across the pulse (20.9 µs per sample), dispersion smearing was 40 µs across a 1 MHz bandwidth and the post-detection time constant was 50 µs. The total intensity data are shown at full resolution, whereas the linear and circular polarization data have been boxcarsmoothed over four time samples. b, Position angle of the linear polarization, plotted wherever the linear polarization was >3.0 times the r.m.s. (root mean square) noise. Representative error bars are ±1.0 the r.m.s. error in the position angle. c, Position angle, with two segments shifted by 90°, plotted together with a representative fit to a Radhakrishnan and Cooke¹⁵ model ($\alpha = 30^{\circ}$, $\beta = 25.5^{\circ}$. $\theta_0 = 91^{\circ} \text{ and } \phi_0 = 263^{\circ}).$

in each sense of circular polarization and a half-power beamwidth of 10'. At zenith angle 10° and galactic background temperature 150 K, parameters typical of the region of sky surveyed, the flux density equivalent to the total system noise was \sim 17 Jy.

During the survey we observed a grid of 14,452 beam areas, with 9' spacing between points, for 39 s each. A filter-bank spectrometer provided 16 adjacent channels of 60 kHz width for each circular polarization. Detected power from the two polarizations was summed for each channel, and the sixteen resulting signals were smoothed with a time constant of 400 μ s, sampled every 300 μ s, digitized to 3-bit precision, and stored on magnetic tape for later analysis. Further details of the searching procedure are contained in ref. 1. The survey observation in the direction of PSR1855+09 was made in October 1984, and confirming observations followed in July and November 1985. By mid-December it was clear that a new millisecond pulsar had been found, and that its period was changing significantly on a timescale of several days. The pulsar's mean flux density at 430 MHz is ~10 mJy.

Starting on 20 December 1985, we have made timing measurements of the new pulsar with equipment and techniques similar to those used to observe PSR1953+29 7 . The Arecibo telescope was used for these observations, usually at 1,400 MHz, with a $2\times32\times250$ kHz filter bank. Because interstellar scintillation causes the signal strength to vary widely (with a decorrelation bandwidth of \sim 8 MHz, a timescale of \sim 40 min, and a peak-tomean flux density ratio approaching 10), we choose an exact observing frequency, somewhere in the range 1,360-1,440 MHz, at the time of each observation. A 32-channel signal averager samples the total-power signals 256 times per pulsar period and records 32 integrated pulse profiles every two minutes. Up to

45 such observations can be made on a given day. Cross-correlation of the observed profiles with a standard profile produces a set of phase delays which are corrected for dispersion, averaged and added to a reference time near the midpoint of the integration to yield an effective pulse arrival time. Based on the variance of dispersion-corrected phase delays, the uncertainties in arrival times for 2-min integrations are between 2 and 15 μs, depending on signal strength. The total-intensity pulse profile is shown in Fig. 1a, together with the linear and circular polarization.

A 15-min observation made with the Very Large Array (VLA) on 28 February 1986, using two 50-MHz bandwidths centred at 1,464.9 MHz and 1,514.9 MHz, found an average pulsar flux density of 1.5 mJy, and provided a position measurement in the FK4 coordinate system of $\alpha(1950) = 18 \text{ h}$ 55 min 13.681 \pm 0.009 s, $\delta(1950) = +09^{\circ}$ 39' 12.80 \pm 0.15". Because the product of the decorrelation bandwidth and the peak-to-mean flux ratio is as large as our total bandwidth, the measured flux over a 15-min period is subject to large statistical fluctuations. Our estimated flux density, therefore, is accurate only to about a factor of two. For these observations we used the radio source 1821 + 07 as a phase calibrator; its position was assumed to be $\alpha(1950) = 18 \text{ h}$ 21 min 41.655 s, $\delta(1950) = +10^{\circ}$ 42' 43.90".

The timing data were analysed using a procedure similar to that described by Rawley et al.⁷. We first determined the best-tit Solar System barycentric period for each available 20-min interval of data. These periods were used to carry out a least-squares solution for the pulsar period in its own rest frame, P, the binary orbital period, P_b , the projected semi-major axis, $a_1 \sin i$ (where i is the angle between the plane of the orbit and the plane of the sky), and a time of passage through the

ascending node. The sinusoidal velocity curve determined from these parameters is superimposed on a plot of the barycentric period measurements at the top of Fig. 2.

Unambiguous pulse numbers could then be assigned to the 1,073 pulse arrival times obtained between 20 December 1985 and 24 May 1986. A least-squares fit yielded the pulsar parameters and orbital elements listed in Table 1. Figure 2 shows

Table 1 Parameters of the PSR1855+09 system

Right ascension (1950.0) $\alpha = 18 \text{ h} 55 \text{ min } 13.6834 \pm 0.0006 \text{ s}$ Declination (1950.0) $\delta = \pm 09^{\circ} 39' 13.278 \pm 0.009''$ $P = 5.362,100,452.39 \pm 0.03 \text{ ps}$ Pulsar period $\dot{P} = (2.1 \pm 0.5) \times 10^{-20} \text{ s s}^{-1}$ Period derivative $DM = 13.2943 \pm 0.0002 \text{ cm}^{-3} \text{ pc}$ Dispersion measure $a_1 \sin i = 9.2307850 \pm 0.0000004$ light s Projected semi-major axis $e = (21.27 \pm 0.08) \times 10^{\circ}$ Eccentricity Orbital period $P_b = 1,065,067.593 \pm 0.004 s$ Longitude of periastron $\omega = 277.10210 \pm 0.33^{\circ}$ $T_0 = 2,446,433.3026117 \pm 0.0114 \text{ JD}$ Time of periastron

post-fit residuals for this solution, plotted as a function of both data and orbit phase. The timing position shown in Table 1 is based on the coordinate system of the PEP740-R ephemeris (J. F. Chandler *et al.*, personal communication). Positions obtained from this ephemeris must be rotated by $\sim 0.4''$ before they can be compared with FK4 coordinates^{8,9}. After this is done, the discrepancy between the VLA and timing positions is about two standard deviations—probably not significant.

The very small period derivative (\dot{P}) observed for PSR1855+09 implies a surface magnetic field strength of $\sim 3 \times 10^8$ G—very close to the values obtained for the other two millisecond radio pulsars^{6,7}, and consistent with binary spin-up models for their evolution (refs 10, 11 and references therein). A small \dot{P} also suggests that the rotational stability of this pulsar, like that of PSR1937+21, is probably very high⁶. This conjecture is supported by the fact that after averaging our timing data to give a single equivalent arrival time for each of the 21 observing days, we obtain a post-fit weighted r.m.s. residual of only 2.6 μ s. Future comparison of timing residuals of PSR1855+09 with those of PSR1937+21 may be able to distinguish effects external to the Solar System (such as a cosmic background of gravitational radiation⁶) from inaccuracies in the Earth's ephemeris or in the realization of atomic time.

Because of the extremely small eccentricity of the orbit of PSR1855+09, relativistic effects will not be readily detectable in its timing data. General relativistic advance of periastron should occur at a rate of $\sim 15''$ yr⁻¹, but with present accuracies it will require a century or more to detect. Some further conclusions concerning statistics of the population of binary radio pulsars are discussed in ref. 3.

On 7 and 18 January 1986 we made phase-resolved polarization observations of the new pulsar at 1,400 MHz, using a procedure similar to that described by Stinebring¹². The mean polarization of this pulsar at 1,400 MHz reaches a maximum of ~10% circular (near the peak of the main pulse) and 10% linear (on the trailing edge). The circular polarization changes sign at the centre of the main pulse and the linear polarization goes to zero between the components of the main pulse and interpulse, indicating the presence of orthogonally polarized radiation^{13,14}.

The position-angle swing of the linear polarization of many pulsars is consistent with a simple model first put forward by Radhakrishnan and Cooke¹⁵, in which the position angle at a particular rotational phase is determined by the projection of the local magnetic field direction onto a plane perpendicular to the line of sight. Assuming a purely dipolar magnetic field structure, the position angle χ is given by 16

$$\tan(\chi - \chi_0) = \frac{\sin \alpha \sin(\phi - \phi_0)}{\cos \alpha \sin \beta - \sin \alpha \cos \beta \cos(\theta - \theta_0)}$$

where α is the angle between the rotational axis and the magnetic dipole axis, β is the angle between the rotational axis and the

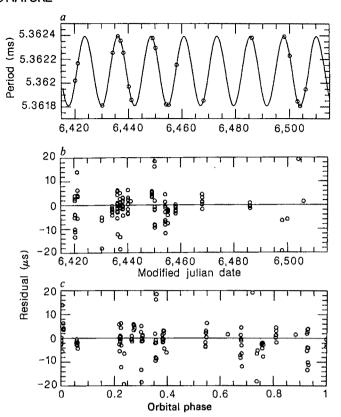

Fig. 2 Summary of PSR1855+09 timing data, 20 December 1985 to 16 March 1986. a, Sinusoidal fit to pulse period measurements (circles) on 21 different days. For the sake of clarity only one period measurement per day is plotted. b, c, Residuals from fit (Table 1) to pulse arrival times, plotted against time in b and orbital phase (fraction of an orbit since periastron passage) in c. Each circle corresponds to 10 min of observing time. No attempt is made to distinguish among data of widely varying quality.

line of sight, and ϕ is the azimuth of the line of sight relative to the projection of the magnetic axis onto the equatorial plane. The angles ϕ_0 and χ_0 are physically uninteresting, as the origin of pulse phase and position angle are arbitrary.

A fit of this equation to the position-angle data is shown in Fig. 1c, where the position angle has been shifted by 90° on the trailing half of the interpulse and the leading half of the main pulse, assuming that this radiation is in an orthogonal polarization state. A least-squares fit for α and β was performed after fixing $\phi_0 = 263^\circ$ and $\chi_0 = 91^\circ$ because of the obvious symmetry point at the centre of the main pulse. Over the range $10^\circ \le \alpha \le 90^\circ$ we find good fits to the main-pulse position-angle sweep for an intercept angle $\alpha - \beta = q\alpha$, where q varies smoothly from 0.2 at $\alpha = 10^\circ$ to 0.1 at $\alpha = 90^\circ$. Although the fit shown is not very good in the interpulse region, the position-angle swing does match the slope of the interpulse data fairly well. Any fit with $\beta > \alpha$ can be ruled out because the observed position-angle gradient has the same sign across the interpulse and the main pulse.

The position angle data are consistent with an interpulse produced at either the same magnetic pole as the main pulse or at the opposite magnetic pole¹⁷. The symmetry of the mainpulse and interpulse morphology, as well as the indication that corresponding components of the main pulse and interpulse are in the same polarization mode, lead us to favour a one-pole model similar to that proposed by Narayan and Vivekanand¹⁸ for PSR0950+08. Their model, in which α is relatively small and we cut across both edges of a hollow cone twice, is in good qualitative agreement with the polarization and pulse morphology data for this pulsar. Such a model is made more likely by the evidence that pulsar beams are elongated in the direction

of latitude and that this elongation is more marked for shorterperiod pulsars¹⁹. The deviation of the interpulse position angle from the simple model considered here may arise from a departure from dipolar magnetic field geometry, magnetospheric propagation effects²⁰, or interpulse emission from a much higher altitude than for the main pulse²¹.

The discovery of a third millisecond pulsar so nearby indicates that millisecond pulsars, although difficult to find, are not rare objects in the pulsar population. As their presumed progenitors—the low-mass X-ray binary systems—are rare, millisecond pulsars may be observable for much longer than the 108-yr lifetimes of the X-ray systems. This, in turn, implies that pulsar magnetic fields may not decay below a level of $\sim 5 \times 10^8$ G within a Hubble time, an idea discussed in detail by other authors^{5,11}. Independent evidence that millisecond pulsars are very old and long-lived comes from the detection of cool white dwarf companions for PSR0655+64 and PSR0820+02 by Kulkarni²², and for the millisecond pulsar reported here by Wright and Loh²³

We thank the staff of the Arecibo Observatory, and in particular A. Wolszczan, for help with the observations and the U.S. National Science Foundation for financial support. We would also like to thank J. H. van Gorkom for providing observing time and technical assistance at the VLA.

Repulsive regularities of water structure in ices and crystalline hydrates

Hugh F. J. Savage* & John L. Finney†

Hydrogen-bonded structures display wide ranges of the various angles (such as O-H···O) and distances (such at H···O) used to describe their intermolecular geometry. For example, O···O distances are found to vary between ~2.5 and 3.2 Å, and the hydrogen bond angles normally vary between 120 and 180°. Although correlations between distances and angles may be found (for example, between H...O distance and O-H...O angle), these geometrical characteristics are generally too 'soft' to be used as stereochemical restraints in, for example, refining the solvent structure in protein crystals. Moreover, although many potential functions exist for describing water-water interactions, none of them is totally satisfactory in reproducing experimental results, even for pure water1. We present here the initial results of an analysis of water structures in high-resolution neutron crystal structures² which is much more successful in rationalizing the stereochemistry of water interactions. Rather than considering the structures in terms of weak, orientation-dependent attractions, a concentration on the repulsive interactions leads to a set of very much stronger stereochemical constraints, which not only rationalize the structures but appear largely to control the orientational correlations in aqueous systems. Looked at this way, water network structures in crystal hydrates and, we suspect, in the liquid itself, become for the first time comprehensible. The approach provides a much firmer base from which to build realistic potential functions to model and simulate solvent structures.

A significant number of atomic-resolution neutron diffraction studies are now available in which the hydrogen (deuterium) atoms can also be located. Figure 1a shows a well-known plot relating to small hydrate crystals3; we see that as the H···O distance of hydrogen bond increases, the mean O-H···O bond angle tends to decrease. However, there is a large scatter in the H-bond geometries about the regression line that can be drawn: some short H-bonds are very bent, while some long ones tend to be very straight. A similar spread of values appears (Fig. 1b) when we restrict ourselves to the H-bond geometries of water molecules in a variety of crystal hydrates (containing between 1 and 18 water molecules per asymmetric unit) and ice polymorphs analysed by high-resolution (≤1.0 Å) neutron diffraction. Rather than draw a regression line as in Fig. 1a, however, we draw a limiting line below which configurations are notwithin experimental error—observed. There is thus apparently an excluded region. This limiting line represents the extreme limits of H-bond bending, which can be thought of as

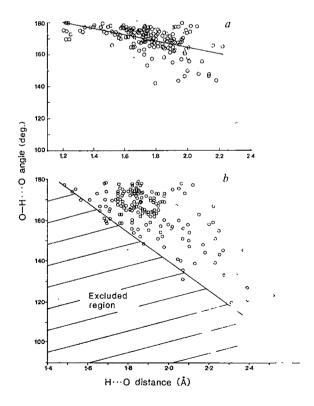

Fig. 1 Plots of O-H...O angle versus H...O distance: a, for H-bonds in small neutron structures (redrawn from ref. 3); b, for water H-bond geometries found in high-resolution neutron hydrate structures, showing the effect of repulsive restraint RR1 (see Fig. 2a) (see ref. 2 for full list of structures and source references).

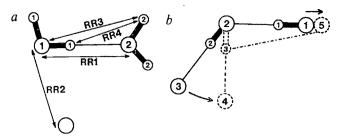

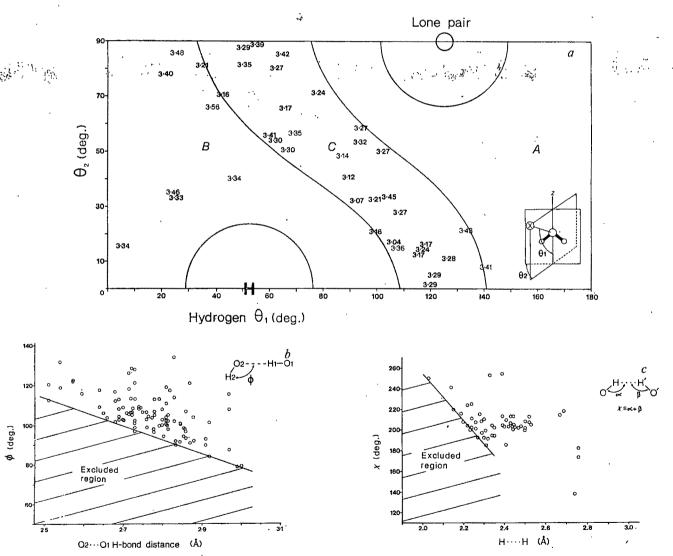

Fig. 2 a, Schematic diagram of the four proposed repulsive restraints: RR1, O···O repulsion of H-bond; RR2, O···O non-bonded repulsions; RR3, H2···O1 oxygen-remote-neighbour-hydrogen non-bonded interaction; RR4, H···H non-bonded repulsion. b, Schematic diagram of how the operation of RR3 relates an increase in H-bond distance to a decrease in O···O··O H-bond angle. If we start with a tetrahedral conformation of O1···O2···O3 with H-bond lengths of 2.76 Å, then on moving O3 to O4 (assuming H-bond linearity), the H3···O1 distance becomes less than the acceptable minimum contact of ~3.0 Å, and to relieve this strain, the O2···O1 H-bond must lengthen (O1 moves to O5), to retain a minimum H3···O1 contact of ~3.0 Å.

characterizing the limits of the O···O repulsions of the water hydrogen-bonded neighbours. We label this 'repulsive restraint' RR1 which is illustrated, together with three other repulsive restraints, in Fig. 2a.

The second repulsive restraint, RR2, describes the significant anisotropy of $O\cdots O$ non-H-bonded contacts, which range from 3.1 to 3.6 Å. Figure 3a shows the minimum $O\cdots O$ next-nearest-neighbour contacts observed in water molecules with respect to the two orientational angles defined in Fig. 3a inset, and can be discussed in terms of three regions. In the 'lone pair' region, A, there are no contacts ≤ 3.5 Å. In the hydrogen-bonding region, B, the minimum contact distance is ~ 3.3 Å, whereas between the lone pairs and hydrogens (region C) a minimum separation of ~ 3.1 Å is observed. These data can be rationalized to a first approximation if we tentatively assign to the three separate regions around the water molecule the following van der Waals' radii: 1.7-1.8 Å in the lone-pair region, 1.6-1.7 Å between the hydrogens, and 1.5-1.6 Å between the lone pairs and the hydrogens.

The third restraint, RR3, relates to the $H2\cdots O1$ remote neighbours (Fig. 2a) and appears to be the key to water molecule

 Γ_{3} . 3 a, $\theta_{1}-\theta_{2}$ orientational angle plot for the non-bonded O···O, C contacts around four-coordinated water molecules in the neutron structures examined. Bold numbers are water-oxygen contact distances (in Å) to oxygens; lighter numbers to carbons. θ_{1} and θ_{2} are the angles of approach of the contact, as defined in the inset. The significance of regions A, B and C to RR2 is discussed in the text. b, Plot of H2—O2···O1 angle (ϕ) versus O2···O1 H-bond distance, showing the effect of repulsive restraint RR3, relating to H2···O1 contacts (see Fig. 2a). In this part of the analysis, the O—H covalent bonds were standardized to 0.8 Å, to enable the approximate centre of the electron density of the hydrogens to be represented. This distance, the numerical value of which is not critical, was chosen on the basis of results from high-resolution X-ray structure analyses. 7 and deformation studies 8-10. c, Plot of the sum (χ) of the O—H···H angles subtended at the hydrogens (see inset) versus the H···H contact distance, showing the effect of repulsive restraint RR4 (see Fig. 2a).

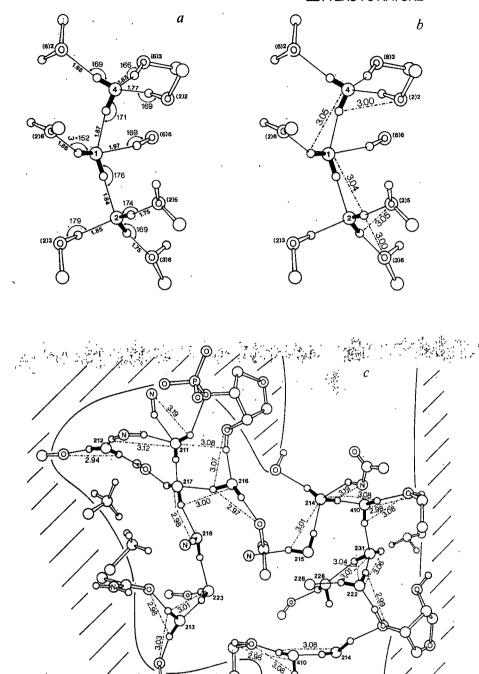

Fig. a, b,Hydrogen-bond networks in a local region of α -cyclodextrin, showing a, the range of Hbond distances (in A) and particularly H-bond angles (in degrees); and b, an explanation of the orientations on the basis of minimum oxygen-remote-hydrogen (H2···O1) contacts (shown in Å) of ~3.0 Å (effect of RR3). c, H2···O1 contacts (in Å) around water molecules in vitamin B₁₂ co-enzyme hydrate, shown in projection.

orientations. Figure 4a shows a region in α -cyclodextrin⁴. The hydrogen-bond distances and angles vary widely within the range shown in Fig. 1. Using the regression line as a target geometry, we would expect the H-bond angle ω (152°) to be greater, as a largely rotational motion of water 1 could be made without significantly affecting the near-linear O1—H···O2 angle. However, experimentally, this does not happen. Figure 4b shows the same region, but with the relevant remote-neighbour $H2 \cdots O1$ distances given, and immediately we may understand the situation: no remote-neighbour $H \cdots O$ distances are found which are ≤ 3.0 Å. Viewed in this way, an attempt to increase ω would begin to compromise the presumably repulsive interaction with the oxygen of water 4.

Figure 4c shows the $H2\cdots O1$ minimum contacts between water molecules in the crystal hydrate of co-enzyme B_{12} (ref. 5

and J.L.F., P. F. Lindley, H.F.J.S. and P. A. Timmins, in preparation), and the same pattern is apparent. These minimum contacts appear to 'fix' the mutual orientations of the water molecules at the expense of distortions of the H-bond geometries. In Fig. 3b, the H2—O2···O1 angle is plotted against the O2···O1 H-bond distance. As in Fig. 1, rather than draw a regression line to represent the mean values, a line representing the minimum values of the H2···O1 contacts (H2···O1 limiting curve) is drawn to give another section through what is presumably an excluded volume of the total configurational space.

The fourth constraint, RR4, relates to the $H \cdots H$ repulsions and Fig. 3c shows a plot of the water $H \cdots H$ repulsive contacts as a function of the angle χ (defined as the sum of the two angles subtended at the hydrogens, see Fig. 3c inset). The shortest water $H \cdots H$ contacts are ~ 2.1 Å and occur when the

O-H groups are arranged more nearly 'head-on': the majority are between 2.3 and 2.4 Å. Again, an excluded region can be specified.

Using these regularities, we can now understand more clearly some structural tendencies shared by ices and hydrates. For example, there are two ways of obtaining a more compact water structure than in ice Ih: by decreasing some of the O···O··O H-bond angles and/or by forming interpenetrating H-bond lattices (for example, at high pressures). By the former method, some of the O···O H-bond distances must increase in order to maintain the minimum H2···O1 contacts (Fig. 2b). These contacts appear to play a dominant role in determining the immediate local water structure. For example, acceptor waters, which form very short H-bonds (down to ~2.5 Å), tend towards a trigonal planar coordination, in order to maintain the H2...O1 minimum contacts of ~3.0 Å (ref. 2). Where longer H-bonds of 2.8-3.2 Å occur, significant distortions from the expected tetrahedral structure are allowed. Thus, in water structures in which the number and strength of the H-bonds are maximized (shorter H-bonds), the H2. O1 minimum contacts tend to enforce a tetrahedral-like structure (for example, in the ice polymorphs).

The exact nature of these interactions is not clear in all cases; however, we can make some proposals which may assist in developing better potential functions for simulation calculations. RR2 can be considered in terms of an angular-dependent van der Waals' radius which is, not surprisingly, larger around the lone-pairs region. The RR3 and RR4 interactions may be understood in terms of assigning a variable, angular-dependent van der Waals' radius to the polar water-hydrogens. Values of ~1.5 Å in the H—O direction and ≤1.0 Å in the O—H direction may be appropriate. This type of model is consistent with the known asphericity of the electron cloud around hydrogens attached to polar groups^{6,7}. More exact values may be obtained from more detailed analyses of the interactions between electron clouds of neighbouring water molecules (for example, by performing detailed high-level quantum mechanical calculations).

In the absence of a full physical explanation of the nature of these interactions, the very clear pattern of excluded regions, with no known significant violations, gives us confidence in using these minimum values as strict constraints in interpreting water organization in crystals (for example, during protein refinement). The 'hardness' of these excluded regions makes them far more reliable than the softer, more indefinite bondangle and bond-length restraints which have been used until now and which, as shown in Fig. 4a, b, can lead to incorrect structures.

The repulsive restraints discussed here can also be used to improve potential functions widely used in computer simulations of aqueous systems. A reasonable model for the nonbonded intermolecular structure will have to take into account the asymmetric character of both the oxygens and the hydrogens; that this has not been done may account for the difficulty in obtaining a satisfactory agreement with experiment¹. We are pursuing the incorporation of repulsive restraints in water potentials for the simulation of liquid water and other chemically and biologically important aqueous systems.

Selenium in western Atlantic precipitation

Gregory A. Cutter* & Thomas M. Church†

* Department of Oceanography, Old Dominion University, Norfolk, Virginia 23508, USA † College of Marine Studies, University of Delaware, Newark, Delaware 19711, USA

The trace element composition of precipitation (rain and snow) provides a way of monitoring anthropogenic and natural emissions to the atmosphere; the subsequent deposition of such emissions (for example, as acid precipitation) can have important effects on aquatic ecosystems. In this regard, the mobilization of selenium by fossil fuel combustion1 and selenium's toxicity2 provide compelling reasons to examine this element's atmospheric transport and removal. Furthermore, recent investigations suggest that atmospheric deposition is an important selenium input to oceanic surface waters^{3,4}. Here we examine data on the concentration and oxidation state of selenium in precipitation over coastal and midocean regions of the western Atlantic Ocean. The results indicate that fossil fuel combustion enriches selenium in wet depositional fluxes to western Atlantic surface waters, and that selenium's oxidation state in precipitation may be a sensitive oxidationreduction (redox) tracer.

Selenium is removed from the atmosphere by processes such as wet deposition, through its association with sub-micrometre aerosols⁵ and the efficient scavenging of these small particles during precipitation events⁶. As a Group VI element, selenium can exist in four oxidation states (-II, selenide; 0, elemental selenium; IV, selenite; VI, selenate). Selenium is thought to be naturally emitted to the atmosphere as volatile dimethyl selenide⁷; selenium dioxide [Se(IV)] or elemental selenium may be released during fossil fuel combustion⁸. In rainwater samples from Japan⁹ and coastal California¹⁰, selenite is the major selenium species; rain and snow in urban Belgium contain variable quantities of both selenite and selenate¹¹. Further studies of selenium's chemical speciation in precipitation may help to identify the sources of atmospheric selenium; elucidate the equilibrium state and kinetics of atmospheric redox reactions, and quantify the contribution of atmospheric deposition to the oceanic selenium cycle.

Precipitation samples were obtained at Lewes, Delaware and High Point, Bermuda, from August 1983 to January 1984 using automated Aerochem Metrics precipitation samplers¹². Rain water was placed in acid-cleaned borosilicate bottles, acidified to pH2 (with HCl), and refrigerated to minimize biological growth. Determinations of selenite selenate, and selenide+ elemental selenium were made using the procedures described in refs 3, 10 and 13; sulphate, sodium and pH were determined using the methods in refs 14 and 15. To evaluate possible artefacts arising from sample collection, two precipitation events were sampled using three different collection devices; the concentration and speciation of selenium from all three systems were within 10% of each other. In addition, artefacts from sample storage appeared to be minimal, as no selenium speciation changes were detected between rain water analysed within hours of collection and that analysed one month later. Thus, the data presented below are assumed to be representative of atmospheric processes and not procedural aberrations.

The sampling site at Lewes receives precipitation which is fairly representative of northeastern United States air masses¹⁶ and winter storm fronts often pass over Bermuda from North America after 1-2-day transit times¹⁷. Thus, the rain water concentration and speciation of selenium collected at these locations may reflect the combined effects of source strengths (marine and continental), and processes which occur during atmospheric transport and deposition. Figure 1a is a plot of total selenium concentration versus sodium at Lewes and Bermuda. The

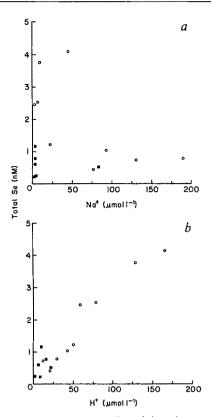

Fig. 1 Total selenium versus sodium (a) and protons (b) in precipitation samples collected at Lewes, Delaware (○) and Bermuda (■). Values for total selenium are based on triplicate determinations, with the procedural precision (expressed as relative standard deviation) not exceeding 3%. The correlation coefficient (r) for a linear regression fit of the total selenium/proton data is 0.9589 (n = 15).

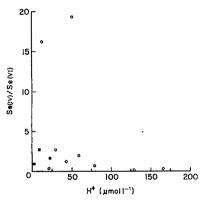

Fig. 2 The ratio of selenite to selenate [Se(IV)/Se(VI)] versus protons in Lewes, Delaware (○) and Bermuda (■) precipitation samples. Determinations of selenite and selenate were made in triplicate, and the procedural precision (expressed as relative standard deviation) did not exceed 7%.

apparent lack of correlation between selenium and sodium indicates that processes generating sea-salt aerosols do not contribute selenium to precipitation. However, there appear to be two distinct groups of precipitation events, those with low selenium-high sodium (marine origin) and those with high selenium-low sodium (non-marine). The low selenium-concentration background is in accord with the presence of uniform concentrations of aerosol selenium in the global marine atmosphere⁵. In contrast, Fig. 1b shows a strong correlation between total selenium and protons. A similar correlation is found between total selenium and excess (non-sea-salt) sulphate (r=0.9505, n=15). Previous studies of western Atlantic precipitation have attributed increased acidity and excess sulphate to

anthropogenic emissions from North America^{16,18} The data shown in Fig. 1b suggest that fossil fuel combustion in North America also contributes selenium to western Atlantic precipitation.

In Fig. 2, the ratio of selenite to selenate in precipitation is plotted against proton concentration. During this study, selenide + elemental selenium was detected in only one sample (Lewes; 28% of the total selenium). Furthermore, with the exception of two samples from Lewes, the range of selenite/selenate values at both sites is small $[Se(IV)/(Se(VI) = 1.26 \pm 0.95,$ n = 10]. The two samples with the highest selenite/selenate ratios came from storms travelling in northerly directions, placing the coal-fired Indian River Station power plant 30 km upwind of the rain sampler. Thus, a local anthropogenic input may account for the enrichment of selenite in these two events. For the remaining samples, the source-type (that is, natural or anthropogenic) cannot be identified on the basis of oxidation state in Fig. 2. If the oxidation states of atmospheric selenium inputs are correctly assigned (as above), then the rates of redox reactions during transport and deposition must be sufficiently rapid to obscure discrete oxidation state signals.

If the results in Fig. 2 are generally indicative of oxidation-reduction equilibrium, then the apparent redox intensity of precipitation, pE (where $pE = -\log [e^-]$), can be estimated using the equation: $SeO_4^{2-} + 3H^+ + 2e^- = HSeO_3^- + H_2O$; $E^0 = 1.075$ V. The pE of 11.50 ± 1.01 (n = 10) calculated in this manner is close to values for the nitrate-nitrogen dioxide and peroxide-oxygen couples reported elsewhere¹⁹. However, more data are needed on the speciation of selenium, as well as other redox couples, in precipitation, to determine more accurately the oxidation intensity of corresponding air masses.

The volume-weighted average selenium concentration (that is, the total selenium normalized to rainfall amount) at Bermuda is <20% of that at Lewes (Table 1). However, the washout

Table 1 Selenium in western Atlantic precipitation

ratios (volume-weighted average concentration in precipitation divided by concentration in air) at the two sites are equally large, suggesting that removal by wet deposition predominates. The wet depositional flux of selenium at Bermuda (Table 1) is similar to the average total deposition estimated from aerosol measurements (38 pmol cm⁻² yr⁻¹) by other workers²⁰ for the same site. Although no independent data are available, the calculated wet depositional flux at Lewes (Table 1) falls between the values estimated by Ross²¹ for remote continental (75 pmol cm⁻² yr⁻¹) and "urban" (840 pmol cm⁻² yr⁻¹) wet deposition. In spite of the large reduction in selenium flux between the coastal United States and Bermuda, this atmospheric input to the central Atlantic is still significant (22% of that due to vertical upwelling; see Table 1). These flux data

support the hypothesis by Measures et al.4 that atmospheric deposition elevates surface-water selenium concentrations in the western Atlantic. Furthermore, selenite is enriched in precipitation over the western Atlantic relative to sub-surface waters (average sub-surface selenite/selenate = 0.09, ref. 21). As a result, inputs of selenite and selenate through wet deposition and upwelling have different effects on parameters such as surface-water residence times for these two species³.

The selenium speciation data obtained for wet deposition suggest that the element may act as a useful tracer of oxidationreduction equilibrium and kinetics. More thorough sample collection and analysis efforts will be required to verify the extent of this equilibrium. In addition, the sequential sampling of

individual storm events at the coast and at multiple sites across the Atlantic should yield data on the kinetics of oxidationreduction reactions affecting selenium. The chemical similarity between selenium and sulphur increase the interest of such studies. The equilibrium between sulphur dioxide and sulphuric acid is affected by the atmosphere's redox intensity (pE). The rate at which this equilibrium is reached controls the long-range atmospheric transport of sulphur, the deposition of sulphuric acid, and thus affects acid precipitation²².

Correlations between stream sulphate and regional SO₂ emissions

Richard A. Smith & Richard B. Alexander

United States Geological Survey, Reston, Virginia 22092, USA

The relationship between atmospheric SO₂ emissions and stream and lake acidification has been difficult to quantify, largely because of the limitations of sulphur deposition measurements. Precipitation sulphate (SO₄) records are mostly <5 yr in length¹ and do not account for dry sulphur deposition2. Moreover, a variable fraction of wet- and dry-deposited sulphur is retained in soils and vegetation and does not contribute to the acidity of aquatic systems^{3,4}. We have compared annual SO₂ emissions for the eastern United States from 1967 to 1980 with stream SO₄ measurements from fifteen predominantly undeveloped watersheds (Figs 1, 2). We find that the two forms of sulphur are strongly correlated on a regional basis and that streams in the southeastern United States (SE) receive a smaller fraction (on average, 16%, compared with 24%) of regional sulphur emissions than do streams in the northeastern United States (NE). In addition to providing direct empirical evidence of a relationship between sulphur emissions and aquatic chemistry, these results suggest that there are significant regional differences in the fraction of deposited sulphur retained in basin soils and vegetation.

The stream SO₄ data (Table 1) are from monitoring stations in the USGS Hydrologic Benchmark Network⁵. Five stations were used to estimate average annual SO₄ yield in the NE, and 10 stations were used in the SE (Fig. 1). Stream SO₄ at these stations is believed to be largely of atmospheric origin^{6,7}. The SO₄ yield for each year from 1967 to 1980 was estimated as the product of the annual discharge-weighted mean SO₄ concentration and mean basin runoff for the 14-yr period. The regional SO₄ yield was estimated as the average of the individual basin yields.

Regional SO₂ emission densities were based on state-level data from two recent sources^{8,9} which used alternative methods of estimating emissions. Regressions against stream sulphate were conducted separately for the two sets of emission data in order to determine the sensitivity of results to the choice of methods. Husar's 'production-driven' estimates are based on

records of the sulphur content and distribution of produced fuels, whereas those from Gschwandtner et al.9 are 'consumption-driven' and are based on fuel consumption records. Emission estimates from Hidy et al. 10 for southeastern Ontario were added to both data sets in calculating NE emission densities and represent ~17% of the regional total. Trends in state-level SO₂ emissions^{8,9} and stream SO₄ concentrations (Table 1) were nearly homogeneous in direction (decreasing in the NE and increasing in the SE) within the defined regions during the study period. Varying the size of the defined regions through the addition or deletion of states near the regional boundaries has relatively little effect on regional emission densities, which, like stream yields, are expressed as areal averages (g m⁻² yr⁻¹).

Regressions of stream SO₄ yield against SO₂ emission density give slope values ranging from 0.14 to 0.25 for various combinations of region and source of emission data (Fig. 2). The results are similar for the two sets of emission data and suggest that,

^{*} Expressed as sulphur.

an average, streams transport $\sim 20\%$ of sulphur emissions in the eastern United States. However, an analysis of covariance¹¹ indicates that, for both sets of emission data, a regression model with a single intercept but regionally separate slope estimates is preferable to other models. Slope estimates for both data sets show significantly higher values for the NE region than for the SE (an average of 24%, compared with 16%). All four regression lines pass close to the origin, a result which supports the assumption that stream SO₄ at these sites is largely of atmospheric origin and comes primarily from sources within the region.

origin and comes primarily from sources within the region.

Johnson et al.¹² have suggested that streams in the southeastern United States might be expected to transport a smaller fraction of deposited sulphur than northeastern streams, on the basis of experiments showing greater sulphur retention in soils typical of the SE. Southeastern soils are predominantly ultisols, which contain subsurface clay horizons with high SO₄-adsorption capacities¹². The hypothesis of greater SO₄ retention in the SE is strongly supported by the regional differences in regression slopes observed in this study, together with SO₄

deposition measurements¹³ for the regions. Comparison of stream SO_4 yields with wet SO_4 deposition estimates (Table 1) gives significantly larger ratios of yield to deposition (Y/D) in the NE. Ratios for the SE are all <1.0, whereas those for the NE are mostly >1.0. The sulphur-adsorbing properties of basin soils are thought to be an important factor controlling the acidification of surface waters because mobility of sulphate in soils is required for the transport of hydrogen ions (as well as base cations) through basin soils to streams^{3,14}.

The regression results and yield-to-deposition ratios presented above can be used to calculate approximate sulphur budgets for the NE and SE (Table 2). Regression slopes for the two regions indicate that 16% of the sulphur emitted in the SE (24% in the NE) is transported by streams, and that the remaining 84% (76% in the NE) is either retained in basin soils and vegetation or is deposited outside the region. If dry deposition is assumed to be equal to wet deposition 15, then median basin retention of SO₄ is 35% of emissions in the NE and 59% of emissions in the SE. Basin retention is considerably smaller,

Table 2 Estimated sulphur budgets for the northeastern and southeastern United States (1980)

		Regional	estimates	
]	NE	SI	3
Budget component	Quantity (g m ⁻² yr ⁻¹)	Per cent of emissions	Quantity (g m ⁻² yr ⁻¹)	Per cent of emissions
SO ₂ emissions	3.7	100	2.4	100
Atmospheric transport out of the region	1.5	41	0.6	25
Total deposition	2.2	- 59	1.8	75
Basin retention	1.3	35	1.4	59
Stream transport	0.9	24	0.4	16

Total deposition is calculated as twice the measured¹³ wet deposition, atmospheric transport of sulphur from the region as the difference between SO₂ emissions and total deposition, and basin retention as the difference between stream SO₄ transport and total deposition.

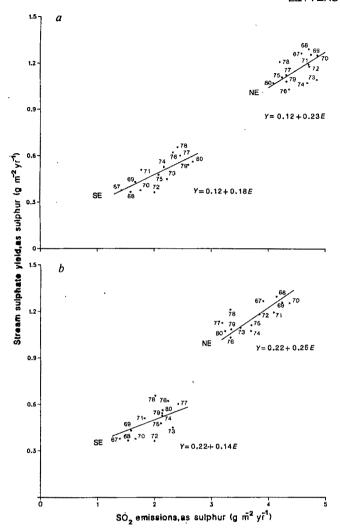

Fig. 2 Average stream yield (Y) of SO₄ at USGS Benchmark stations in the eastern United States, plotted against regional SO₂ emission density (E) for the years 1967-80 (shaded numbers). Plots are presented for two recent sets of emission estimates^{8,9}, based on alternative methods of estimating the sulphur content of combusted fuels (a, production-driven emissions⁸; b, consumptiondriven emissions⁹). Both emissions and stream yield of sulphur decreased in the NE but increased in the SE during the 1967-80 period. Analyses of covariance for both sets of emission estimates result in a two-slope, one-intercept model with smaller slopes for the SE than for the NE. All slopes are significant at $\alpha = 0.01$. Intercepts are not significantly different from zero at $\alpha = 0.05$.

however, for certain of the NE basins with non-ultisolic soils. Average retention for Maine, New York and Pennsylvania, for example, is only 14%. Assuming that dry and wet deposition are equal, atmospheric transport from the region is 41% in the NE and 25% in the SE. These estimates of extra-regional transport bracket a previously reported estimate 16 (30%) for sulphur transport from eastern North America, thus supporting the earlier estimate.

There has been continuing uncertainty concerning the quantitative reltionship between atmospheric SO₂ emissions and sulphur deposition in North America and, to a lesser extent, in Europe^{15,17}. This uncertainty stems from the shortage of longterm deposition records on which to base correlative studies as well as from problems with the measurement of dry deposition. The relationship between SO₂ emissions and aquatic transport of SO₄ has remained even less clear because of a shortage of empirical data on the retention of wet- and dry-deposited

sulphur in a variety of soil types⁶. The results described here indicate that an approximately linear (and nearly proportional) relationship exists between SO₂ emissions and stream transport of atmospheric sulphur in the eastern United States. These results appear to demonstrate the response of stream SO₄ to both increases and decreases in emissions over a wide range of emission densities. There is evidence that the slope of the relation between SO₂ emissions and stream SO₄ is somewhat smaller in the SE due to greater basin retention of SO₄. Greater SO₄ retention may initially serve to reduce the acidifying effects of SO₄ deposition in the SE, but gradual accumulation of SO₄ in soils may lead to increased stream transport of SO₄ in the future. Additional variability in the effects of acid deposition can be expected to result from differences in the ability of basins to neutralize acids by supplying base cations^{6,19}. Budgets for the environmental fate of atmospheric SO₂ emissions, including basin retention of SO₄, could be further refined by reliable measurements of dry deposition.

We thank J. Turk, G. Oehlert and A. Johnson for helpful discussions, and O. Bricker, H. Lins and J. Pickering for reviewing the manuscript.

Dating ice-wedge growth in subarctic peatlands following deforestation

Serge Payette, Line Gauthier & Ivan Grenier

Centre d'études mordiques, Université Laval, Québec, Canada G1K 7P4

Ice wedges are one of the most prominent periglacial features in the zone of continuous permafrost, and constitute significant climatic and palaeoclimatic markers 1-4. Active ice wedges are found in areas with a mean annual air temperature below -6 °C (ref. 5), although recent data⁶ suggest that they can form at -3.5 °C. Most of the reports⁷⁻⁹ dealing with ice wedges have referred to Arctic and Antarctic conditions, whereas subarctic ice wedges from glaciated areas are poorly known. Ice-wedge inception and spatial development as orthogonal and polygonal nets were inferred generally from theoretical analysis 10,11 and sparse detailed field work 7,8. Because ice wedges occur also in subarctic permafrost

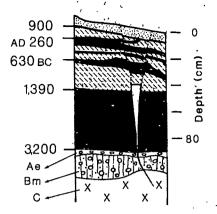

Fig. 1 Stratigraphy of a peat section from outside the studied quadrangle, showing the relationship between radiocarbon-dated wood layers and ice-wedge growth. The formation of this 8-cm-wide ice began sometime after AD 900 (extrapolated from radiocarbon-dated growth curve) when spruce (black) and Sphagnum (hatched) cushions, always intermingled with spruce branches and leaves, were replaced by a snow-free lichen-Dicranum cover (dotted), The layer from 3,200 to 1,390 BC is made of intermingled spruce and Sphagnum. From 3,200 BC to AD 900, this site was snow-protected because of continuous spruce-Sphagnum growth. Ae, Bm and C at the bottom of the peat profile refer to pedogenetic horizons.

peatlands^{12–15}, the combined use of macrofossil peat stratigraphy and radiocarbon dating may yield useful information concerning their development. Here we present the first account of such a framework, derived from the analysis of marginal ice wedges developed in the eastern Canadian Subarctic. We show that the inception and spatial development of epigenetic ice wedges in some subarctic peatlands occurs after the natural removal of coniferous vegetation, which induces snow-free conditions, permafrost aggradation and, ultimately, deep frost cracking. We have dated ice wedges indirectly, using combined curves of rates of spruce removal and ice-wedge growth.

In North America, subarctic ice wedges are found mostly in peat plateaus and palsa bogs¹²⁻¹⁴. Their presence is generally inferred from the polygonal network which dissects the extensive, windswept lichen-heath vegetation occurring above the fossil peat. A closer look at the upper peat stratigraphy where epigenetic ice wedges develop reveals in most cases a charcoal horizon or a non-charred wood layer indicative of the former presence of coniferous vegetation. As long as the coniferous vegetation was able to maintain itself on the peatland, buffered thermal conditions prevailed in the peat substrate because of snow insulation. Removal of the coniferous cover induces snowdrift conditions and creates snow-free sites that change the overall thermal regime, favouring deeper cold penetration into the peat substrate. This close relationship between coniferous vegetation, snow conditions and thermal characteristics of substrates forms the basis of our hypothesis, which states that ice wedges found in many subarctic peatlands in eastern Canada, where continental deglaciation occurred during early to mid-Holocene times^{16,17}, were formed sometime after site defores-

A small insular Sphagnum bog in the Clearwater Lake area, subarctic Québec ($56^{\circ}30'$ N, $75^{\circ}30'$ W; mean annual air temperature ≈ -5 °C), has been used to test the hypothesis. The peat stratigraphy of the bog (Fig. 1) shows a cyclic alternation of Sphagnum and spruce (Picea mariana (Mill.) BSP.) which persisted for several thousand years 18; cessation of cyclic replacement occurred during the past 2,000 years, particularly in the most exposed sites where a lichen-Dicranum-heath vegetation now covers the fossil peat. Ice wedges develop in these sites and form an irregular polygonal pattern at the surface. The

measurement of 26 polygonal cells separating individual icewedge lineaments has indicated an average dimension of 7×9 m, although many polygons were incompletely formed. We have studied in detail ice wedges developed under a lichen-Dicranumheath cover in a representative section of the selected peatland. Within a 1,444-m² quadrangle (38×38 m), the ice wedges were mapped and measured (Fig. 2). Correlation between ice-wedge yertical length and width was established by direct observation in manually excavated peat sections. Ice wedges were distinguished from frost cracks, also filled with ice but confined to the active layer, by a detailed study of their melting pattern during summer 1982. The surface topography of the quadrangle was determined with an electronic level (GDD Instrumentation Inc.); and the thickness of the peat deposit (ranging from 85 to 260 cm) was evaluated by coring at several sites. The coniferous cover of low krummholz (stunted spruces) has been mapped, and the uppermost fossil-wood layer laying immediately under the lichen-Dicranum-heath cover was radiocarbon dated at nine different sites within the quadrangle (Fig. 2). The ¹⁴C dates were calibrated to calendar dendroyears¹⁹, to determine regression rates of coniferous vegetation and ice-wedge age (Fig. 3).

Frost cracks were particularly extensive in the study area in March-April 1982 and 1983. In 1982, the cracks were 36 ± 6 cm long, (n=133), and the depths of the active layer in July, August and September were, respectively, 29 ± 2 cm (n=29), 40 ± 5 cm (n=113) and 42 ± 4 cm (n=42). In 1983, the frost cracks were slightly longer, 39 ± 6 cm (n=52). Their spatial pattern was irregular, sometimes linear or arcuate, but rarely polygonal (Fig. 2).

Ice wedges were found at 49 ± 6 cm (n = 153) from the peatland surface; that is, at the present maximum depth of the active layer. The wedges were made of white foliated ice including vertically oriented air bubbles and occasionally peat (Fig. 4a). The width of the ice wedges ranged from 0.1 to 48 cm, and was

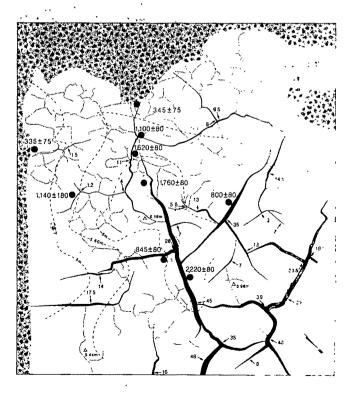

Fig. 2 Distribution of ice wedges (black) and frost cracks (dotted lines) on lichen ground cover surrounded by spruce krummholz (grey pattern). Numbered arrows denote maximum ice-wedge widths (cm). Dashed lines, contours of the peatland surface in m above lake level; open triangles, bench marks; large dots, ¹⁴C dates.

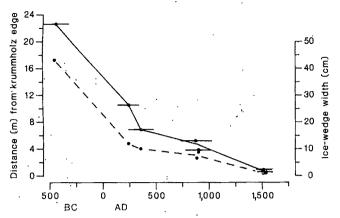

Fig. 3 Regression of coniferous vegetation (solid line), based on position of radiocarbon-dated fossil wood layers (calibrated to calendar years) relative to present krummholz edge. Horizontal bars indicate the 2σ (95% confidence) intervals for the calibrated ¹⁴C dates. The curve of ice-wedge width versus time (broken line) is similar to the conifer regression curve, which gives a reliable method for ice-wedge dating in subarctic peatland ecosystems.

highly correlated (r = 0.95) with vertical length (maximum icewedge length 190 cm). The ice wedges were slightly arcuate, especially at the bottom tip. Loose ice crystals (depth hoar?) were predominant at the bottom tip of large ice wedges. The basic spatial pattern consisted of individual lineaments of variable length and width, orientated in all directions. Most icewedge lineaments are independent features that converge occasionally in a semi-orthogonal pattern. Their horizontal growth always stops at the intersection of a nearby ice wedge, so that the longest ice wedges are those that do not merge into one another (Fig. 2). An extensive oblique layer of foliated ice formed within the mineral substrate was also observed at the intersection of two ice wedges, at a site where the peat deposit is shallower (Fig. 4b). This ice shows a structure similar to that of the wedges, an indication that its presence is associated with ice-wedge formation. Some very short but relatively wide ice

wedges have also developed, which supports the idea that horizontal growth stops when two ice wedges meet. Only two closed ice-wedge polygons were observed; they were characterized by relatively large lineaments compared to those found elsewhere.

Before ~500 BC, the peatland was entirely covered by coniferous vegetation (based on radiocarbon dating of the uppermost wood layers). Along the NE-SW direction, where two independent ice-wedge lineaments have developed in similar environments (Fig. 2), spruce regression began earlier at the higher site, and progressed radially at different rates towards the modern krummholz edges (Fig. 3). A highly significant correlation (r = 0.98) was found between ice-wedge width and distance in metres from the modern krummholz edge; thus, the curve of maximum ice-wedge width measured near the radiocarbon-dated sites shows a pattern similar to the spruce regression curve (Fig. 3). This suggests a direct relationship between deforestation and ice-wedge inception; the age of an ice wedge is therefore very close to the age of deforestation. However, two radiocarbon dates were excluded from the analysis. The 14 C date of $845 \pm$ 80 yr BP obtained from a sample close to the oldest deforested site (Fig. 2) may appear to contradict the radial pattern of spruce regression. But this date came from a charcoal sample associated with a palaeo-Indian camp fire located, probably for convenience, on the open lichen ground. All the fragments of three small boulders thought to have surrounded this fire were also recovered from the peat deposit, just above a 25-cm-wide ice wedge. This suggests that the fire was ignited from wood of nearby provenance, probably at the edge of the 850 yr BP spruce cover. Additionally, it indicates that ice-wedge activity has caused boulder burial along the thermal cracks. The 14C date of 800 ± 80 yr BP appears to be anomalous according to position along the ice-wedge lineament; this may be related to the uncertain position of the sample, associated with problems of surface disturbance during peat excavation. All of the radiocarbon dates (except 845±80 yr BP) confirm the radial pattern in spruce regression: from the highest site, at an altitude > 6.0 m above the Clearwater Lake level, to the modern krummholz edges, generally at an altitude <5.0 m, spruce regression has progressed radially but at different rates according to site exposure (Fig.

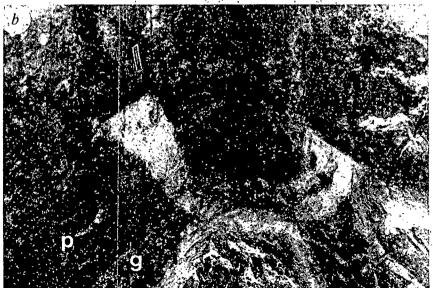

Fig. 4 a, Section of a 48-cm-wide ice wedge (ruler, 15 cm); ice-wedge vertical length, 190 cm. In March 1983, the left part of this ice wedge was opened by a thermal crack ~0.10-0.15 mm wide and 220 cm long. b, Intersection of two ice wedges, showing an extensive oblique layer of foliated ice formed within the gravelly substrate (g). The peat layer (p) is ~1 m thick.

3). The radiocarbon dates of the uppermost wood layers correspond therefore to maximum ages of ice wedges, assuming that they began to develop immediately after the removal of coniferous vegetation. Note that ice wedges do not open each winter, particularly in such marginal permafrost areas, given that in Arctic sites only 40% of the ice-wedge population is active each year⁷. In April 1983, for example, only a few ice wedges were active, although conditions for thermal contraction were particularly favourable. One 48-cm-wide ice wedge was opened by a crack $\sim 0.10-0.15$ mm wide and at least 220 cm deep (Fig. 4a); the crack was located not at the centre, but rather along one side of the ice wedge, as has frequently been observed in the study area.

The inception and spatial development of ice wedges in the subarctic requires particular microclimatic conditions that simulate the Arctic environment, where ice wedges occur extensively in mineral lowlands. These conditions are usually found in ombrotrophic peatlands, with Sphagnum peat as an insulating blanket. In general, ombrotrophication appears to be the necessary step for permafrost aggradation in subarctic peat-lands^{12,14}, occurring some time before the microclimatic condi-, occurring some time before the microclimatic conditions for ice-wedge formation are met. In northern Canada. permafrost invasion in peatland is associated with a change in drainage conditions which is emphasized in peat stratigraphy by a shift towards ombrophilous (Spagnum, Picea, Ericacaea) species^{12,14}. Although regional conditions may vary² development of epigenic ice wedges coincides generally with treeless, somewhat dried, raised peatlands characterized by a very low peat growth rate; spruce removal and expansion of windswept lichen cover seem to be the ultimate prerequisites for such a development, at least in the snowier eastern Canadian Subarctic. Subsequent ice-wedge development at these sites appears to be a slow and irregular process. Mean annual icewedge growth rates measured in this study vary from a maximum of 0.18 mm yr⁻¹ to a minimum of 0.04 mm yr⁻¹ (Fig. 3), a very low figure compared to modern Arctic and Antarctic ice-wedge growth rates^{7,9}. The average dimensions of these subarctic polygons are very small compared to Arctic polygons, which range from 15 to 40 m (ref. 3). Because these ice wedges have formed in a climatically marginal environment, they developed slowly, allowing us to follow the changing spatial arrangement with time. Their horizontal growth towards polygon formation did not show any defined order in time, as proposed elsewhere¹¹; in fact, the spatial growth of individual ice wedges, based on their distribution today (Fig. 2), suggests that the different segments of an ice-wedge polygon may vary in age. Whether this time-sequence in polygon formation is the rule remains to be substantiated. Our data indicate that subarctic ice-wedge expansion is a palaeocological event closely tied to local vegetation development. Thus, the onset of ice-wedge development in the subarctic may have been directly controlled by Holocene deforestation, a long-term, time-transgressive ecological process operating at the microscale. It implies that subarctic ice wedges could have responded directly to climate forcing only when the habitat development had reached a critical threshold emphasized by deforestation. That is why the palaeoclimatic significance of subarctic ice wedges should be interpreted cautiously.

We thank Professor J. Ross Mackay (University of British Columbia) for discussion and for very useful suggestions on an earlier draft. This study has been financially supported by the Ministère de l'Éducation of Québec (FCAR Program) and the Natural Sciences and Engineering Research Council of Canada (NSERC).

Hydrocarbon shows and petroleum source rocks in sediments as old as 1.7×10^9 years

M. J. Jackson, T. G. Powell, R. E. Summons & I. P. Sweet

Division of Continental Geology, Bureau of Mineral Resources, Geology and Geophysics, GPO Box 378, Canberra, ACT 2601, Australia

We report the discovery of indigenous 'live' oil in ~1.4-Gyr-old rocks in the McArthur Basin of northern Australia. Previously reported occurrences of indigenous Precambrian oil are <1 Gyr old¹⁻⁵. Potential petroleum source rocks in the McArthur Basin range in age from 1.4 to 1.7 Gyr and were deposited in marine and lacustrine environments. In parts of the basin they have been buried sufficiently deeply to have generated hydrocarbons. They span the period corresponding to the appearance of eukaryotic organisms, and because of their low degree of thermal alteration, they provide a valuable resource for the study of primitive biota through their hydrocarbon biomarkers. The hydrocarbon composition of the oil is consistent with a derivation from organic matter of prokaryotic origin. These results show that exploration of previously ignored mid-Proterozoic sediments may lead to the discovery of new reserves of oil.

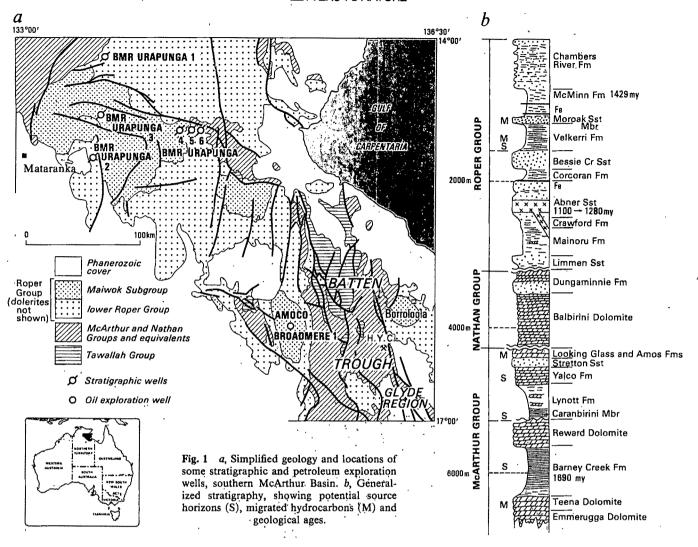

Despite the occurrence of commercial Proterozoic oil and gas fields in the Soviet Union, Oman and China^{1.5}, rocks of this age are not generally considered to be likely sources of petroleum⁶. The McArthur Basin (Fig. 1a) contains an unmetamorphosed, structurally simple sedimentary sequence. A sequence of stromatolitic and evaporitic carbonates with interbedded shales (McArthur and Nathan groups) is overlain unconformably by quartz arenites and interbedded shales (Roper Group)⁷. The sequence ranges in age from 1,690.23 Myr for the Barney Creek Formation8 of the McArthur Group to 1.429 ± 31 Myr for the McMinn Formation of the Roper Group (Fig. 1b). The presence of extensive unmetamorphosed carbonaceous shales, widespread microbial remains 10-15 and reports of bitumen and gas in the McArthur Group¹⁶ prompted an investigation of the hydrocarbon potential of the basin.

Organic-rich sediments, at various stages of hydrocarbon generation (maturation) have been found at five different stratigraphic levels (Fig. 1b, Table 1). McArthur Group sediments were deposited in lacustrine and perhaps very shallow marginal marine environments in fault-bounded grabens'. The thick organic-rich shales of the Barney Creek Formation are intimately interbedded with talus breccias and sabkha-like evaporite cycles, indicating deposition in arid climates in shallow playas or nearshore lagoonal complexes¹⁷. The Yalco Formation contains thin (1-4 m) organic-rich shales (Table 1, Fig. 1b) within a series of

French, H. M. The Periglacial Environment (Longman, London, 1976).

variable cherty, stromatolitic carbonates and minor sandstones deposited in ephemeral lakes in a dominantly humid climate¹⁸. The Roper Group, in contrast, comprises a laterally extensive sequence of well-sorted quartz arenites and grey shales deposited in marine conditions. Depositional environments range from inner shelf for the arenites to low-energy, deeper marine environments for the organic-rich sediments of the Velkerri Formation (Table 1).

Oil bubbled from thin laminae of siltstone enclosed in black mudstone of the Velkerri Formation at a depth of 345.4 to 346.5 m in the BMR Urapunga no. 4 stratigraphic hole (Fig. 1). Preliminary GCMS (gas chromatography/mass spectrometry) analyses of the oil and marginally mature source rocks in the McArthur Basin show a preponderance of hydrocarbons derived

from organic matter of prokaryotic origin (see Fig. 2). Analyses of the C₁₂₊ hydrocarbon fraction from the oil revealed a mixture dominated by n-alkanes of low relative molecular mass without odd-over-even predominance, 1- and 2-methylalkanes, ω-cyclohexyl alkanes and a series of unresolved mixtures, possibly of monomethylalkane isomers. The last may be similar to those found in Upper Proterozoic oils from Oman¹⁹. Only a trace of pristane was detected, and sterane and hopane biomarkers were absent. In contrast, less mature Velkerri sediments contained low amounts of pristane, phytane, hopanes and steranes. Lowmaturity sediments from the Barney Creek Formation contained abundant pristane, phytane, extended acyclic isoprenoids, hopanes and traces of steranes.

These results demonstrate for the first time the presence of

'live' oil and petroleum source rocks in 1,400-1,670-Myr-old sediments, and record the oldest unequivocally indigenous hydrocarbon biomarkers so far identified. They significantly change our estimate of the volume of sediments that may contain petroleum in Australia and elsewhere. Although the oil and sediments contain hydrocarbons which imply prokaryotic precursors, in general, they are not significantly different from many Phanerozoic samples, emphasizing the importance of the contribution of prokaryotic organic matter to source rocks of all ages²⁰ Subtle compositional differences in the contents of acyclic and cyclic biomarkers between the Velkerri Formation (marine) and the Barney Creek Formation (lacustrine) illustrate that environmental differences are reflected in the composition of sedimentary organic matter, even in the Proterozoic. In all the McArthur sediments, the extremely low abundance of steranes (biomarkers for eukaryotic organisms²¹) compared with hopanes, supports the concept of the rise of the eukaryotes in the latest Proterozoic (that is, after 1,400 Myr)²². However, this evidence remains equivocal until environmental influences on organic matter composition in these sediments can be determined.

Amino acid epimerization in planktonic foraminifera suggests slow sedimentation rates for Alpha Ridge, Arctic Ocean

S. A. Macko & A. E. Aksu

Department of Earth Sciences, Memorial University of Newfoundland, St John's, Newfoundland, Canada A1B 3X5

Interpretations of the palaeoclimatic and palaeooceanographic histories of the Arctic Ocean^{1,2} have been hampered by conflicting chronologies obtained using different dating methods. Magnetostratigraphic and micropalaeontological data¹⁻⁴ have suggested a sedimentation rate of ~1 mm kyr⁻¹, whereas the rate indicated by amino acid epimerization analyses on foraminifera⁵ is an order of magnitude higher. To establish a firm chronology for cores from the Alpha Ridge, Arctic Ocean, and to help resolve the controversy between the ages assigned by different dating methods, we have carried out detailed amino acid epimerization analyses on planktonic foraminifera Neogloboquadrina pachyderma sinistral from a long gravity core. Assuming that the temperature in the Arctic Ocean did not exceed 3 °C during the past 1 Myr, the alloisoleucine/isoleucine (alle/Ile) ratios obtained from this core suggest a sedimentation rate of ~1 mm kyr⁻¹, supporting previous magnetostratigraphic and micropalaeontological studies.

This study was primarily based on amino acid epimerization analyses on planktonic foraminifera extracted from core CESAR 83-102 (85°38' N, 111°07.1' W), raised from a depth of 1,495 m on the Alpha Ridge, Arctic Ocean (Fig. 1). The core includes down-core sequences of sediments typical of previously studied Arctic Ocean cores (Fig. 2). Three lithostratigraphic units (K-M) identified in this core are fully discussed elsewhere⁶, and are briefly described here: lithological unit M is a partially bioturbated, foraminifera-rich, yellowish sandy to silty mud, with up to three pink-white carbonate hardground layers. Unit L consists of foraminifera-poor, light brown sandy-silty mud, and unit K is a partially bioturbated, dark brown silty-sandy mud with variable numbers of foraminifera. High-resolution seismic profiles show smooth, flat-lying reflectors over the core site⁷. Detailed examination of X-radiographs shows the absence of internal sedimentary structures usually associated with resedimentation. The presence of widespread bioturbational sedimentary structures suggests that the sediments recovered in this core represent pelagic or hemipelagic deposition. The magnetostratigraphic data from this core² indicate that the boundary between the Brunhes and Matuyama magnetochrons lies in unit K at ~87 cm depth. This boundary is generally accepted to occur at 0.73 Myr (ref. 9).

Amino acid epimerization reaction rates are species-dependent^{10,11}; therefore, only monospecific samples of N. pachyderma sinistral were used for the analyses. This taxon, however, shows large morphological variations and includes several morphotypes, such as N. polusi and N. cryophila, that are considered by some^{4,12} to be separate species. Therefore, only the fourchambered quadrate forms of N. pachyderma sinistral were used for the amino acid analyses. Twenty-seven levels were analysed in CESAR 83-102, each sample comprising a 1-cm-thick slice of the core. Despite much greater sensitivity in detection level for the amino acid technique, enabling smaller samples to be analysed, larger sample sizes were used to reduce potential laboratory contamination and to ensure sample integrity and homogeneity. About 1,000 specimens (~10 mg) were handpicked from each sample; foraminiferal shells were ultrasonically cleaned in distilled water three times and each sample was rinsed with distilled water twice. Samples were sealed under nitrogen with a stoichiometrically related excess of hydrochloric acid to yield final solutions of 6 M HCl, which were then hydrolysed for 24 h at 100 °C. Portions of the hydrolysate were

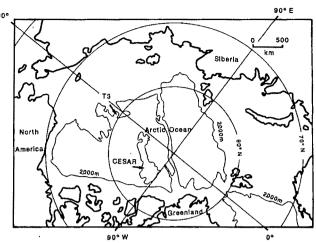

Fig. 1 Map of the Arctic Ocean showing the locations of the CESAR and T-3 ice camps.

analysed by stepwise isocratic elution with baseline separation of the alloisoleucine/isoleucine pair, fluorescence detection and peak integration on an ion-exchange HPLC (high-pressure liquid chromatograph) with a detection limit of ~ 10 pM (ref. 13). Triplicate analyses show that the reproducibility is ± 0.025 in the alle/Ile value. For chronostratigraphic calibration, alle/Ile was determined on two additional samples of N. pachyderma sinistral, extracted from well-dated ash layers 2 and 3 of the North Atlantic cores K708-1 and K708-7, respectively. Results of these analyses as well as an interlaboratory sample of Saxidomus sp. (ILC-A) are presented in Table 1. This

Table 1 Ratio of alle/Ile in *N. pachyderma* sinistral from Arctic Ocean core 83-102 and Atlantic Ocean cores K708-1 and K708-7, corresponding to volcanic ash layers 2 and 3 respectively¹⁴

standard is reported for comparison as recommended by Wehmiller¹⁵.

The plot of alle/Ile in N. pachyderma from CESAR 83-102 against depth reveals two regions of linearity (Fig. 3). The upper 13 samples show a constant increase in alle/Ile to \sim 23 cm depth in the core, and this data set displays a highly significant correlation ($r^2 = 0.83$; Pearson r, 0.01 level). The second zone extends from \sim 23 to 93 cm depth. Linear regression over this region shows a significant correlation (0.05 level), with an r^2 value of 0.31. Sediments between 47 and 81 cm depth in the core were barren of foraminifera (Fig. 2). The alle/Ile value at the intersection of these two regions is 0.229, and is comparable to that observed elsewhere 10,16,17 . The exact nature of the change in slope between these two regions is not fully understood. A variation in protein content (free versus bound) or the presence of more than one type of protein with different resistance to

degradation or associated rates of epimerization may be the cause¹⁶.

It has been demonstrated that the epimerization reaction of isoleucine

L-isoleucine
$$\xrightarrow{k_{\text{lle}}}$$
 D-alloisoleucine (1)

obeys first-order reaction kinetics¹⁷⁻¹⁹. The reaction rate constants k_{Ile} and k_{alle} are temperature-dependent and are governed by the Arrhenius equation:

$$k_{\text{Ile}} = A e^{(-E_a/RT)} \tag{2}$$

where A is the species-dependent Arrhenius frequency factor¹¹, E_a the genus-dependent activation energy¹⁷⁻¹⁹, R the gas constant and T the temperature (K). The rate constants for the North Atlantic core samples can then be calculated using a solution to the differential rate expression²⁰:

$$\ln \left\{ \frac{1 + \frac{\text{aIle}}{\text{Ile}}}{1 - K' \frac{\text{aIle}}{\text{Ile}}} \right\}_{t} - \ln \left\{ \frac{1 + \frac{\text{aIle}}{\text{Ile}}}{\frac{1 - K' \text{aIle}}{\text{Ile}}} \right\}_{t=0} = (1 + K') k_{\text{Ile}} t \quad (3)$$

where $K' = k_{\text{alle}} = 1/K_{\text{eq}}$, the inverse of alle/IIe at equilibrium, and t is the time. Although alloisoleucine may be present in

living foraminifera and isoleucine may generate alloisoleucine during acid hydrolysis, these contributions (t = 0 term in (3)) are negligible^{21,22}.

The value for K_{eq} is ~1.3-1.4 (refs 17, 20, 22). Taking this value to be 1.4 (refs 20-22), with ages for ash layers 2 and 3 of 65,000 and 340,000 yr BP (ref. 14), respectively, the forward rate constants for epimerization in these two samples are calculated to be 1.551×10^{-6} and 6.803×10^{-7} yr⁻¹, respectively, using measured alle/Ile values (Table 1). An additional rate constant of 1.545×10^{-6} yr⁻¹ is calculated using published data⁵ from the same core, K708-7 (alle/Ile = 0.078, age = 50,000 yr BP, depth = 140 cm). Ages calculated using first-order reversible kinetics of epimerization in marine fossils are found to be optimal for samples with aIle/Ile ≤ 0.25 (refs 16, 20-23); because the value in ash layer 3 is near this limit, the alle/Ile and derived rate constant for this sample are not used for further calculations. The Arrhenius frequency factor ($\log A$) is calculated to be 15.70 using the average of the remaining two rate constants and assuming an activation energy of 113.4 kJ mol⁻¹, which was calculated from a bulk foraminiferal sample¹⁷. This value is nearly identical to the value of 15.77 calculated²⁰ from a North Atlantic core. From these calculations, the relationship between forward epimerization rate constant and temperature for N. pachyderma can be expressed as:

$$\log k_{\text{He}} \, \text{yr}^{-1} = 15.70 - 5.939 / T \tag{4}$$

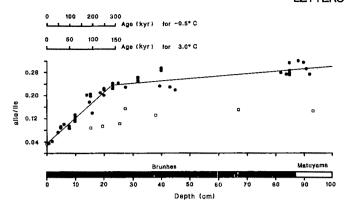

Fig. 3 Epimerization of isoleucine in N. pachyderma sinistral versus depth in core 83-102. Age scale discussed in text, palaeomagnetic scale from ref. 2. \square , from ref. 5, re-plotted based on the Brunhes/Matuyama boundary as the reference point.

Present-day Arctic water temperatures vary from −0.5 °C in the Canada Basin and the Alpha Ridge bottom waters to a maximum in the water column not exceeding +3 °C (ref. 24). First-order epimerization rate constants based on the above temperature range are 8.194×10^{-7} and 1.548×10^{-6} for -0.5 and 3 °C, respectively. Relative ages of sediment can then be calculated using equation (2) (Fig. 3). For example, the sample at 20 cm depth, with an alle/Ile of 0.214 (average of 3 analyses) yields ages of 256,100 and 135,600 yr BP for the maximum- and minimum-temperature rate constants. These ages give sedimentation rates of 0.8-1.5 mm kyr⁻¹ for the Alpha Ridge region of the Arctic Ocean.

This deposition rate is consistent with previous magneto-stratigraphic and biostratigraphic studies 1-4,8,12,24-26, but conflicts strongly with the conclusions of the recent amino acid epimerization study⁵ of the Arctic Ocean core T3-67-11. These authors⁵ have argued that a significant portion of the foraminifera analysed from their core were reworked, and that the alle/Ile measured on the deepest sample (260 cm) was closest to the in situ ratio in this core. Consequently, their age estimate, using calculations similar to those presented here, was based solely on this sample. The rate constant derivation for their estimate was based on benthic foraminifera C. lobatulus. There is no evidence for significant reworking of fauna in studied CESAR cores^{2,6,8}. Palynological data² from a long CESAR core show several first-appearance and last-appearance data of dinoflagellate and pollen and spore taxa in the appropriate sequence, generally supporting little reworking of fauna and flora. It has been demonstrated 6.24 that there is a strongly correlatable downcore sequence of 13 lithological units in >500 cores collected from the Arctic Ocean. Several studies have indicated that there are also correlatable faunal and floral abundance and assemblage variations associated with the lithostratigraphic units2-The paleomagnetic data from several cores from the Arctic Ocean have shown the presence of normal and reversed polarity chrons that are correlated with known magnetic timescales 1,2,25,26. Core T3-67-11, studied by Sejrup et al.5, shows litho-, bio- and magnetostratigraphic variations similar to other cores from the Arctic Ocean^{1,4}. Therefore, the assumption that most foraminifera from core T3-67-11 are reworked may not be warranted.

The foraminifera analysed from core T3-67-11 (ref. 5) show a down-core increase in alle/Ile to a depth of 120 cm. This trend is similar to that observed in CESAR core 83-102 (Fig. 3). The reason for the difference in the slopes of the two data sets is not clear. A variation of this magnitude requires a decrease of \sim 3-5 °C in the average temperature of epimerization for T3 with respect to CESAR sites. Assuming that foraminifera recovered from this core were not reworked and that the average bottom water temperature was -0.5 °C, the alle/Ile values reported by Sejrup et al.⁵ yield respective sedimentation rates of ~ 1.9 and 2.6 mm kyr⁻¹ for samples from 33 and 35 cm depth in T3-67-11. These rates are only slightly higher than the value of 1.6 mm kyr⁻¹ predicted by the palaeomagnetic data from this core¹. We recognize that a single sedimentation rate for the entire Arctic Ocean is unlikely. Based on the above calculations. the sedimentation rates in the Canada Basin (T3) are slightly higher than those calculated for the Alpha Ridge (CESAR); however, these rates are 10-15 times slower than that suggested by Sejrup et al.5.

The amino acid data presented in this paper independently demonstrate a slow sedimentation rate (~1 mm kyr⁻¹) for the Alpha Ridge region of the Arctic Ocean, supporting previous magneto- and biostratigraphic timescales. Through detailed multidisciplinary investigations, the chronology of the Arctic Ocean sediments is believed to have been resolved. A reliable chronology is an important prerequisite in studying the palaeoclimatic and palaeooceanographic histories of the Arctic Ocean and its role in Northern Hemisphere glacial/interglacial cycles.

We thank M. J. Keen and H. R. Jackson of the Bedford Institute of Oceanography for making the CESAR 83-102 samples available and K. Pulchan for assistance in laboratory measurements. This study was supported by the Natural Sciences and Engineering Research Council of Canada. Acknowledgement is made to the donors of The Petroleum Research Fund, administered by the American Chemical Society, for partial support. W. F. Ruddiman provided North Atlantic samples from cores K708-1 and K708-7 and J. F. Wehmiller supplied the interlaboratory standard ILC-A. We thank J. F. Wehmiller, J. A. Welhan, D. J. W. Piper and C. Pereira for critical comments.

Thermal and mechanical constraints on the lithosphere beneath the Marquesas swell

Karen M. Fischer*†, Marcia K. McNutt* & Loren Shure†

* Department of Earth, Atmospheric and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA † Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

The Marquesas Islands, like most active or recently active hotspot chains, lie on anomalously shallow sea floor, and their subsidence history points to a fundamentally thermal origin for the swell¹, as do heat flow and subsidence data for the swells beneath Bermuda² and Hawaii³.⁴. Here we apply a new linear filtering technique to geoid height and depth anomaly data over the Marquesas, to constrain the depth to the high-temperature, low-density material responsible for elevating the swell. We determine an isostatic compensation depth of $45\pm5\,\mathrm{km}$ for the swell, and best-fitting values for lithospheric flexural rigidity and island load density of $5\times10^{22}\,\mathrm{N}$ m and 2,700 kg m $^{-3}$, respectively. The swell's shallow compensation depth and low flexural rigidity call for anomalously high temperatures within the lithosphere 5,6 .

Crough and Jarrard¹ have computed an isostatic root depth of 30 ± 40 km for the Marquesas swell using a geoid height-depth anomaly transfer function. Their result suggests anomalously high temperatures well into the lithosphere, as isostatic compensation depth provides a fairly direct estimate of the depth to the thermal anomaly². Their study is compatible with the low flexural rigidity of 4×10^{22} N m for the Marquesas derived by Cazenave et al.⁷, given that the thickness of the elastic plate supporting intraplate volcanoes has been shown to be thermally

controlled. However, the transfer function method, and other current techniques for estimating swell compensation depth, use assumed values for swell height and width taken from geoid or depth anomaly data. In the Marquesas, the overlap in wavelength between the isostatically compensated swell and the mechanically supported islands makes it difficult to obtain estimates of swell height that are unbiased by island-related topography.

In the present study we apply a new method for estimating swell compensation depth to updated depth anomaly and geoid height maps over the Marquesas. The technique, described more fully in ref. 9, does not require initial estimates of swell amplitude or wavelength, nor does it require that the swell and islands be separated in the spectral domain.

The two primary data sets discussed here are seafloor depth anomalies and geoid height anomalies computed between 160 and 125° W, and 5 and 30° S, an area loosely covering French Polynesia. As we are interested only in hotspot signatures, we attempt to remove from the data all effects of non-hotspot-related processes.

Bathymetry at 5' intervals from the Synbaps data set¹⁰ were averaged to a new spacing of 15' and then corrected for sound velocity variations with a quadratic fit to the Matthews tables¹¹ (L. Wixom, personal communication). The effect of sediment loading was removed according to the empirical relation given in ref. 12, using sediment thicknesses measured from ref. 13. Finally, we accounted for thermal subsidence due to the cooling of the oceanic lithosphere using the depth-age relationship for the North Pacific from ref. 14. Seafloor ages were inferred from the isochron locations of refs 1, 15 and H. W. Menard (unpublished data), and the fracture zone identifications of ref. 16. We estimate the maximum errors in the depth anomaly map for the Marquesas (Fig. 1a) to be less than the 250-m contour interval.

Geoid height data are from the GEOS-3 and Seasat altimeter missions as compiled in ref. 17, at a 15' spacing. Components of the field with wavelengths >4,000 km were eliminated by subtracting the observed field up to degree 10 using the Gem-9

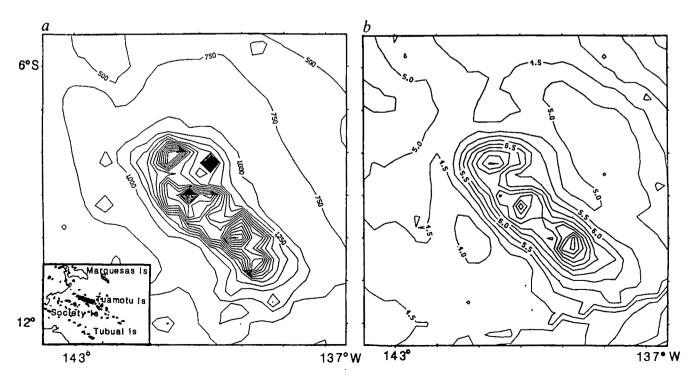

Fig. 1 Maps of reduced depth (a) and geoid (b) anomaly over the Marquesas Islands. a, Contour interval 250 m. The inset shows the major bathymetric features in the area of French Polynesia between 160 and 125° W, and 5 and 30° S (after ref. 1). The single contour in the inset is at 5 km depth. b, Contour interval 0.5 m. Note the flexural moat signatures to the north-east and south-west of the islands.

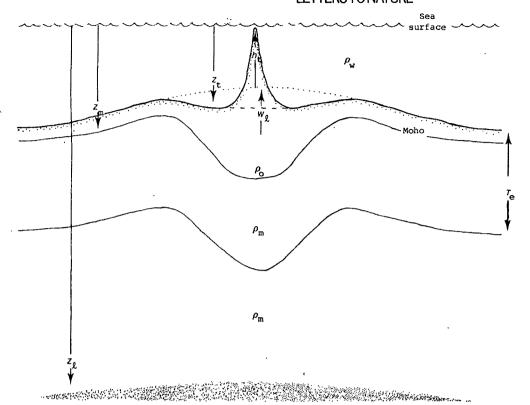

Fig. 2 Schematic cross-section of a swell (from ref. 9). The densities of sea water, volcanic rock and the mantle are $\rho_{\rm w}$, $\rho_{\rm 0}$ and $\rho_{\rm m}$, respectively. The height of the surface load is $h_{\rm t}$, superimposed on the height of the swell, $w_{\rm l}$. Average depth to the sea floor, Moho and swell compensation (shaded, density $\rho_{\rm l}$) are $z_{\rm l}$, $z_{\rm m}$ and $z_{\rm l}$, respectively. $T_{\rm e}$ is the thickness of the elastic plate.

coefficients¹⁸ for the spherical harmonic expansion of the Earth's geoid, and the data were then corrected for the decrease in geoid height due to thermal cooling with age using the geoid heightage relationship of ref. 19 and the North Pacific thermal parameters of ref. 14. At this point the residual geoid showed a long-wavelength NE-SW trend over the Marquesas, in addition to the swell and island signatures. This feature was removed by subtracting the best-fitting plane (in the least-squares sense) from the data between 144 and 136.5° W, and 5 and 12.5° S, leaving the residual geoid shown in Fig. 1b.

Our method for estimating the compensation depth of intraplate swells, explained in more detail in ref. 10, assumes an elastically compensated island topography, h_i , superimposed on a swell with amplitude w_i above normal seafloor depth, due to a sub-plate load with thickness h_i at an average depth z_i , which is the effective compensation depth of the swell (Fig. 2). The observables are the total age-corrected geoid anomaly, N_i , and the total age- and sediment-corrected depth anomaly, $h = h_i + w_i$. If we were to make the false assumption that the observed geoid is due only to the compensation of the observed topography at the Moho by elastic flexure of the oceanic crust, we would predict a geoid anomaly \hat{N}_i , which we define as

$$\hat{N}(k_{x}, k_{y}) = \frac{G(\rho_{0} - \rho_{w})}{gk} \left\{ e^{-2\pi k z_{t}} - \frac{e^{-2\pi k z_{m}}}{1 + k^{4}\alpha} \right\} (H_{t} + W_{1})$$

$$= F_{1}(k) \cdot H(k_{x}, k_{y})$$
(1)

where $\alpha = (2\pi)^4 D/((\rho_{\rm m} - \rho_0)g); \ D = ET_{\rm o}^3/12(1-\nu^2);$ Young's modulus $E = 8 \times 10^{10} \ {\rm N \ m^{-2}}; \ T_{\rm c}$ is the elastic plate thickness; Poisson's ratio $\nu = 0.25; \ k_x$ and k_y are the horizontal wavenumbers; $k = (k_x^2 + k_y^2)^{1/2}; \ \rho_0, \ \rho_{\rm w}$ and $\rho_{\rm m}$ are the densities of volcanic rock, water and mantle, respectively; G is the gravitational constant; g is the acceleration due to gravity; z_i is the average depth of topography; $z_{\rm m}$ is the average depth of the Moho; and upper-case letters are the Fourier transforms of their lower-case counterparts.

By subtracting \hat{N} from the observable N, we obtain a form of reduced geoid anomaly, N_R , which in turn enables us to infer

the swell topography, W_1 :

$$W_{1}(k_{x}, k_{y}) = gk/G \left\{ \left(\frac{\rho_{0} - \rho_{w}}{1 + k^{4}\alpha} + (\rho_{m} - \rho_{0}) \right) e^{-2\pi k z_{m}} - ((\rho_{m} - \rho_{w}) + (\rho_{m} - \rho_{0})k^{4}\alpha) e^{-2\pi k z_{1}} \right\}^{-1} N_{R}(k_{x}, k_{y})$$

$$= F_{2}(k, z_{1}) \cdot N_{R}(k_{x}, k_{y})$$
(2)

The filter F_2 corrects for the compensation falsely assumed in \hat{N} and N_R , and provides an estimate of swell amplitude independent of island topography.

Our method, then, is to assign values for D, ρ_0 , ρ_m , z_t and z_m , the geophysical parameters in the filter F_1 which describe the geoid signature due to plate flexure. We apply the filter F_1 to observed depth anomaly data to obtain N, and then we subtract N from the total observed geoid N, which gives us N_R . We then assume a value of z_1 , apply the filter F_2 to N_R , and obtain an estimate of the swell topography. The best-fitting z_1 values are those which generate profiles of predicted swell topography that match the swell outline seen in the total observed topography. We then test a given value of z_1 in two dimensions by subtracting the predicted swell topography from the observed depth anomalies. The remaining topography should show only the volcanic islands and the signature of their flexural compensation.

Values of z_1 between 25 and 55 km were tested in 5-km increments, along with many values of ρ_0 and D. Load densities between 2,500 and 2,800 kg m⁻³ were considered to be reasonable^{20,21}, although the chemistry of the Marquesas²² suggests that values in the upper end of this range are the most plausible. Values of flexural rigidity were varied from the low value of 2×10^{22} N m suggested by McNutt and Menard²⁰ for the Cook and Tuamoto islands, up to 10^{23} N m. In all cases ρ_m was set to 3,300 kg m⁻³, z_m to 11 km and z_t to 6 km.

The parameter values that produce the best fit to the observed swell (Fig. 3a) and yield a residual topography with clear island signatures (Fig. 4) are $z_1 = 45 \pm 5$ km, $D = 5 \times 10^{22}$ N m and $\rho_0 =$

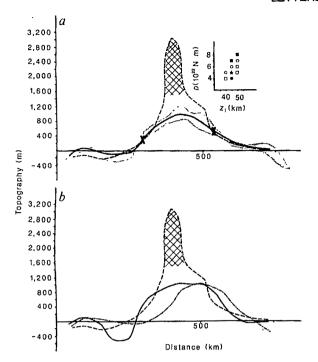

Fig. 3 a, Profiles of observed topography (dashed line) and swell predicted by $z_1 = 45$ km, $D = 5 \times 10^{22}$ N m and $\rho_0 = 2,700$ kg m⁻³ (solid line). The cross-hatched peak gives an example of a typical island feature superimposed on the swell, and the shading indicates the profiles of the envelope of plausible parameter values, shown in the inset ($\rho_0 = : \oplus$, 2,800; \square , 2,700; \bigcirc , 2,600; \boxtimes , 2,500 kg m⁻³; \bigstar , best-fitting parameters). The positions of the flexural moats seen in the observed geoid are shown by crosses (see also Fig. 4). Note that the observed topography here and in b has been shifted downwards by a constant value of 500 m. b, Profiles of two models whose predicted swells do not fit the observed swell topography (dashed line) as well as do the models in a. Solid line, $z_1 = 50$, $D = 5 \times 10^{22}$ N m, $\rho_0 = 2,600$ kg m⁻³; dash-dot line, $z_1 = 40$ km, $D = 5 \times 10^{22}$ N m, $\rho_0 = 2,700$ kg m⁻³.

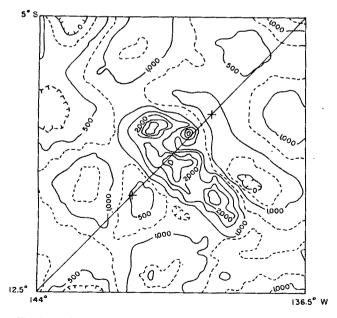

Fig. 4 Residual topography over the Marquesas Islands produced by the preferred values, $z_1 = 45$ km, $D = 5 \times 10^{22}$ N m and $\rho_0 = 2,700$ kg m⁻³. Note the signatures of the volcanic islands and their flexural compensation. The diagonal line shows the locations of the profiles in Fig. 3, and the crosses correspond to the moat positions seen in the observed geoid. Solid contours are at 500-m intervals, dashed contours at 250-m intervals.

2,700 kg m⁻³. The diagonal line in Fig. 4 indicates the location of the profiles in Fig. 3. The only assumption made in fitting predicted swell profiles to observed topography is that off-centre, shorter-wavelength features, such as the dotted area in Fig. 3a, are mechanically compensated islands. Given the ambiguity in separating island and swell contributions near the crest of the swell, preference was given to those models which best matched the flanks of the observed topography, plus or minus a constant value. The approximate locations of the flexural moats were obtained from the observed geoid (Fig. 1b), and allowance was made for their signature in fitting the predicted swell to observed topography profiles. Bathymetric highs corresponding to island locations, a clear flexural moat and an absence of broad highs or lows corresponding to the swell were the features sought for in the residual topography maps.

Surrounding the preferred model is an envelope of parameter values which produce less adequate fits to the swell profile (shown in the shaded area in Fig. 3a) and similar residual topography patterns. The range of acceptable flexural rigidity values within this envelope (shown in Fig. 3a inset) represents the error bars on the best-fitting flexural rigidity value of 5×10^{22} N m, and is largely constrained by the 15' spacing of the data values. An examination of the parameter envelope suggests that for a given surface load density, an increase in compensation depth may be roughly balanced by an increase in flexural rigidity. Alternatively, increasing z_1 or D offsets a decrease in ρ_0 . For instance, for the value of $\rho_0 = 2,800$ kg m⁻³ used by Cazenave et al.⁷ and our preferred compensation depth of 45 km, we obtain their flexural rigidity of 4×10^{22} N m. For comparison, Fig. 3b shows two models which lie outside the envelope of best-fitting parameters.

We also checked the fit of predicted swell heights to observed topography for profiles to the north-west and south-east of those shown in Fig. 3. Over the islands to the north we obtain an identical range of best-fitting parameters. To the south, however, models with deeper compensation depths and larger flexural rigidities are called for both by swell profiles and by the apparent widening of the island moat seen in Fig. 4. Given the younger ages of the islands in this area²³, heat from a lithospheric source would have had less time to elevate lithospheric isotherms conductively, resulting in a thicker apparent lithosphere than is observed in the north.

A compensation depth of 45 km certainly suggests the presence of anomalously buoyant material within the lithosphere. If we equate the geoid anomaly due to an infinitesimally thin layer at z_1 =45 km with the geoid anomaly due to a uniform column of low-density material⁹, the upper boundary of the low-density mass extends well into the upper half of the lithosphere, perhaps to within several kilometres of the surface, depending on the assumed thickness of the column. The actual depth distribution of the low-density material is, however, notably non-unique, and so we look to thermal modelling to shed some light on the significance of z_1 . Some of the Marquesas swell signature may be due to chemically defined low-density material, but as subsidence data¹ and low flexural rigidities suggest that thermal anomalies probably dominate, here we will address only possible thermal models.

Timescales associated with pure conduction are too long to explain the Marquesas swell. Assuming a lithospheric thickness of 70 km, ~20 Myr (at least twice the age of the oldest Marquesas volcanism²³) is required for a thermal anomaly to propagate from the base of the lithosphere to at least 45 km depth. Furthermore, if the base of the conducting region is allowed to migrate upwards as the lithosphere warms, the excess mantle heat flux must be at least four times normal in order to obtain plate thinning rates consistent with the age of the Marquesas²⁴.

Thermal structures produced by simple models of large-scale convection beneath the lithosphere are also incapable of explaining the shallow compensation depth. Calculations involving convection of a constant-viscosity material beneath a conducting

lithosphere of normal thickness (70 km) produce apparent compensation below the base of the plate²⁵, too deep to explain the observed value of 45 km, and decreases in the thickness of the conducting layer will not sufficiently diminish the calculated compensation depths25. However, Robinson et al26 suggest that convection within certain non-uniform viscosity structures may produce thermal anomalies below 70 km depth which merely mimic compensation at depths shallower than the conducting lid thickness. More complex viscosity models may produce an apparent compensation depth at 45 km without the necessity of invoking a thinner conducting lid beneath the Marquesas.

Alternatively, Fleitout et al.27 have proposed that if one accounts for both the temperature and pressure dependence of viscosity, a mantle heat source is liable to create convective instabilities which will erode the base of the lithosphere. This process may continue until the anomalously warm material encounters an abrupt decrease in lithospheric density, such as at the base of the basalt-depleted zone at ~40 km depth²⁸. According to this model, the 45-km compensation indicates that the lithosphere beneath the Marquesas Islands has been thinned to the maximum possible extent.

Using a linear filtering technique which requires a minimum of assumptions about swell height and wavelength9 we obtain a compensation depth for the Marquesas swell of 45 ± 5 km, a density of 2,700 kg m⁻³ for the volcanic islands, and a flexural rigidity of 5×10^{22} Nm for the lithosphere. While our flexural rigidity value is comparable to that of Cazenave et al.7, our compensation depth is somewhat deeper and more tightly constrained than the results of Crough and Jarrard¹. These low values for compensation depth and flexural rigidity call for anomalously high temperatures within the lithosphere and can be used to constrain models for the formation of hotspot swells.

We thank Jim Marsh for providing the geoid data, Linda Meinke for assistance with preparing the geoid and bathymetry databases, and Barry Parsons, Steve Daly, Luce Fleitout and Beth Robinson for helpful comments. H. W. Menard provided previously unpublished isochron identifications. This project was funded by NSF OCE-8409157 and ONR N00014-82-C-0019. Woods Hole contribution 6089.

An enantiornithine bird from the Lower Cretaceous of Queensland, Australia

R. E. Molnar

Queensland Museum, Queensland Cultural Centre, South Brisbane. Queensland 4101, Australia

Current classification of birds recognizes four subclasses: the Archaeornithes, the Enantiornithes, the Odontornithes and the Neornithes. Three of these subclasses were proposed during the nineteenth century, but the Enantiornithes was proposed only five years ago, based on material from the Lecho Formation (Maastrichtian) of Salta Province in Argentina¹. Further material from Asia (Mongolia) and North America (Mexico) has been referred to the Enantiornithes², all of it from the Campanian. Now, in addition, a small tibiotarsus found in the Lower Cretaceous (Albian) of Queensland not only represents the first bony material of Mesozoic birds from Australia, but is also the first reported occurrence of an enantiornithine bird in the Lower Cretaceous.

The unique structure of the distal articulation of the enantiornithine tibiotarsus, with a transversely elongate medial condyle and a markedly narrower lateral condyle, identifies this tibiotarsus as enantiornithine. The specimen (QM F12992) was recovered from a limestone flag of the marine Toolebuc Formation. It was found on Warra Station, on the east side of the Hamilton River, near Hamilton Hotel, west Oueensland, Further details of the stratigraphy and locality are given elsewhere³. The tibiotarsus was one of several small tetrapod elements recovered by acetic acid solution of the limestone and inspection of the residue. It was associated with plentiful small teleost remains as well as remains of other fish, turtles, ichthyosaurs and a pterosaur3.

The tibiotarsus indicates a bird the size of the European blackbird Turdus merula, or the American robin Turdus migratorius, and shows distinctions from the Salta enantiornithine material which render it desirable to erect a new genus

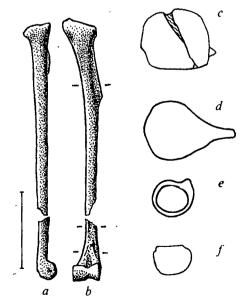

Fig. 1 The tibiotarsus (QM F12992) of Nanantius eos, gen. et sp. nov., in medial aspect (a) and anterior aspect (b). c, The head in proximal aspect; d, e, f, cross-sections of the shaft (with the extent of the internal cavity indicated only in e) at the three levels marked in b. Scale bar, 1 cm.

and species for this oldest-known enantiornithine. Hitherto, the only trace of birds from the Australian Mesozoic has been feathers found at Koonwarra, Victoria (Albian)⁴⁻⁶. These feathers are all small, about 2 cm long⁴⁻⁶ and hence are consistent, at least, with a bird about the size of that represented by the Hamilton tibiotarsus. Other previously reported bird material⁷ from the Australian Mesozoic seems to be dinosaurian.

The enantiornithine tibiotarsus is unique in the narrow intercondylar sulcus and unequal development of the distal condyles¹. The medial condyle is elongate while the lateral condyle is narrow, about half the length of the medial. No theropod dinosaur tibiotarsus (or astragalus) shows this: the condyles are more nearly equally developed, as in birds other than enantiornithines¹. The theropod tibia is distinguished by a short but prominent tibial crest. The Hamilton tibiotarsus has condyles and an intercondylar sulcus like those of the enantiornithines and lacks the tibial crest. Ornithischian dinosaurs have neither a tibiotarsus nor an ascending process of the astragalus, both found in the Hamilton tibiotarsus.

Those pterosaurs with a tibiotarsus have more evenly developed distal condyles which are more pulley-like in form⁸. The pterosaur astragalus has a distinct posterior groove⁹, and the epicondyles are offset in that a line drawn between them is inclined, not perpendicular, to the long axis of the element⁸. The tibia and fibula are fused in pterosaurs⁹. The unequal development of the distal condyles, epicondyles that are not offset, a separate tibia and fibula and the absence of a posterior groove indicate that this tibiotarsus is not derived from a pterosaur. These features indicate that it pertains to an enantior-nithine, and hence to a bird.

Class Aves Subclass Enantiornithes Family?*

* No families have yet been formally proposed for the Enantiornithes; however, in view of the treatise on this group by C. A. Walker (manuscript in preparation) it would be inappropriate to propose families here.

Nanantius, gen. nov.

Type species: Nanantius eos sp. nov.

Type specimen: QM F12992, an isolated left tibiotarsus (Fig. 1).

Locality: North-east paddock of Warra Station, Queensland. Stratigraphy: Toolebuc Formation.

Age: Albian. 10

Diagnosis: A small enantiornithine, smaller than the smallest known from Salta and about the size of Alexornis antecedens, tibiotarsus more slender than any from Salta and similar in proportions to that of Alexornis, fibular crest relatively longer and stronger (Fig. 1d) than in the tibiotarsi from Salta, distinct ascending process of astragalus, marked depression anterior to fibular crest proximally, medial condyle more nearly cylindrical than in any other described enantiornithine.

Etymology: The generic name derives from the Greek $\nu\alpha\nu\sigma\varsigma$, dwarf, and $\dot{E}\nu$ - $\alpha\nu\hat{\tau}i\sigma\varsigma$, opposite, used here in reference to the subclass Enantiornithes. The specific name derives from the Greek $\dot{\eta}\dot{\omega}\varsigma$, dawn, in reference to the earlier occurrence of this specimen than those of other enantiornithine taxa.

The tibiotarsus is preserved in two portions not sharing a contact, one 27 mm long, comprising the proximal two-thirds of the element, and the other, 9 mm long, the distal part. The entire tibiotarsus was probably no more than 40 mm in length. Comparison with the tibiotarsi from Salta clearly indicates that both pieces pertain to a single element. The subrectangular proximal articular face is lengthened transversely (Fig. 1c). The head is expanded, and overhangs anteriorly. The long, low fibular crest extends well down the shaft (Fig. 1b): proximally it merges with the head, leaving a marked concavity just below

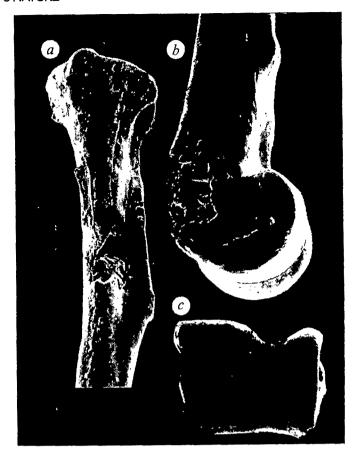

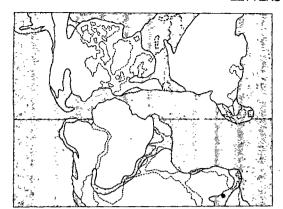

Fig. 2 The tibiotarsus of *Nanantius eos* (QM F12992). a, Proximal portion in anterior view; b, distal condyles in medial view; c, in distal view. Not to scale.

the head and anterior to the crest (Fig. 2a). A much lower crest lies on the anterior side of the shaft, presumably a part of the anterior cnemial crest (Fig. 1a). The lateral cnemial crest is absent (as in the Salta tibiotarsi).

A low crest lies at the medial edge of the anterior face of the shaft, just distal to the break (Fig. 1e). The distal portion of the tibia is fused to the astragalus, leaving no discernible joint (Fig. 2b). The long axis of the astragalar portion is nearly perpendicular to the long axis of the tibial shaft. The medial condyle is elongate and cylindrical in form, whilst the lateral condyle is narrower and with an articular surface formed like the basal part of a cone (Fig. 2c). The groove between the condyles is deeply V-shaped. The ascending process is broad and shallowly concave (Fig. 1f), with a low projection marking its apex. Breakage reveals that the shaft was hollow throughout, with thin walls (Fig. 1e).

The slender construction of the tibiotarsus may be related to the small size of this bone. However, the form of the medial condyle and distinctness of the astragalar ascending process may not be. The latter character is probably plesiomorphic for birds, in view of the evidence for their descent from small theropod dinosaurs, and hence to be expected in an early member of the class.

The unique and recognizable structure of the enantiornithine tibiotarsus clearly apparent here indicates reference of this tibiotarsus to the Enantiornithes. This tibiotarsus differs from the enantiornithine tibiotarsi from Salta in having a narrower and relatively longer anterior cnemial crest and an elongate, rather than approximately square, proximal articular face. The Salta tibiotarsi have medial condyles that constrict slightly towards their medial terminations, while that of Nanantius does not. Nanantius also shows the fibular crest extending proximal

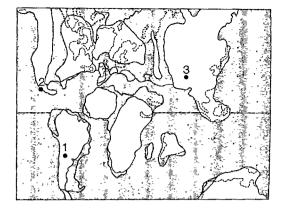

Fig. 3 Distribution of enantiornithines. Lower Cretaceous occurrences (left): Queensland, Nanantius. Upper Cretaceous occurrences (right): 1, Salta, Enantiornis and unnamed taxa; 2, Baja California, Alexornis; 3, Mongolia, Gobipteryx.

to the head and the astragalar ascending process, neither of which is apparent on the Salta material. The only preserved tibia of Gobipteryx minuta is very incomplete and from a hatching specimen11, and hence cannot be satisfactorily compared with that of Nanantius. Only the proximal portion of the tibiotarsus of Alexornis antecedens is preserved¹², and this agrees in both size and proportions with that of Nanantius. However, the proximal part of the shaft in Alexornis is straight, whilst in Nanantius it curves medially (as is found in the Salta tibiotarsi). As in Alexornis, the fibular crest extends all the way up the shaft to the head, and the anterior and posterior faces of the crest are concave in section. The proximal internal articular surface is swollen, as in Alexornis, but shows a distinct posterior overhang lacking in that genus. Both cnemial crests are found in Alexornis, but only the anterior in Nanantius. Thus, Nanantius eos can be distinguished from the other enantiornithines known from comparable material, and this, together with its greater age, lends confidence to the conjecture that it may also be distinct from Gobipteryx.

Enantiornithines are known from the Maastrichtian of Argentina (Enantiornis leali and four other as yet undescribed taxa¹), the Campanian of Mexico (Alexornis antecedens¹²), the Campanian of Mongolia (Gobipteryx minuta¹¹) and the Albian of Australia. The reported occurrence of enantiornithine birds on four continents (Fig. 3), and ranging from the late early Cretaceous throughout the late Cretaceous, indicates that these birds were probably more widespread in the late Mesozoic than has hitherto been recognized. In addition, it emphasizes the widespread distribution of birds as a whole in the Lower Cretaceous, and provides another example of a bird in this period.

This discovery also suggests a link between the Australian Cretaceous vertebrate fauna and that of South America. Such a link has been suggested previously from the occurrence of allosaurid dinosaurs^{13,14} and similar ceratodontid lungfish¹⁵ on the two continents.

Much assistance has been provided in the study of this specimen by Drs N. Fraser, K. Campbell, P. H. V. Rich and R. Wild, and especially by Mr C. A. Walker, through whose courtesy I was able to examine undescribed material from Salta, Argentina. Mrs M. Norrie and Mr S. M. Van Dyck assisted in the collection and development of this material. Financial support of field work was provided by the Australian Research Grants Scheme.

Oxytocin induces morphological plasticity in the adult hypothalamo-neurohypophysial system

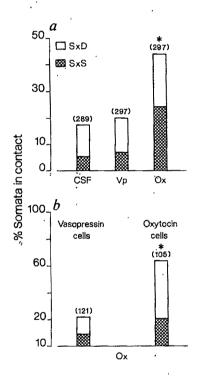

Dionysia T. Theodosis, Catherine Montagnese, Floreal Rodriguez, Jean-Didier Vincent & Dominique A. Poulain

INSERM, U176, Unité de Recherches de Neurobiologie des Comportements, Rue Camille St Saëns, Bordeaux, F33077 Cedex, France

The hypothalamo-neurohypophysial system offers a unique example in the adult mammalian central nervous system (CNS) of a functional and structural plasticity related to a physiological state. During lactation, oxytocin neurones evolve a synchronized electrical activation which permits pulsatile hormone release at milk ejection1. At the same time, in the supraoptic (SON) and paraventricular nuclei, glial coverage of neurones diminishes, so that large portions of their surface membrane become directly juxtaposed; synaptic remodelling also associates pairs of neurones through the formation of common presynaptic terminals²⁻⁵. These structural changes, reversible after weaning4, affect exclusively oxytocinergic neurones⁵ and could facilitate their synchronized electrical activity. As several observations suggest that oxytocin itself is released centrally6-8, we have examined the effect of prolonged intracerebroventricular infusions of oxytocin on the structure of the SON of non-lactating animals. We report here that the peptide indeed engenders the structural reorganization characteristic of the oxytocin system when it is physiologically activated. Similar infusion of vasopressin has no effect. Our observations thus demonstrate that a central neuropeptide can induce anatomical changes in the adult CNS, and suggest that oxytocin can regulate its own release by contributing to the dramatic restructuring of the nuclei containing the neurones responsible for its secretion.

Our experiments were performed on primiparous Wistar rats from our colony 1 month after weaning their first litter. The

Fig. 1 Electron micrographs of oxytocinergic neurones in the supraoptic nucleus (SON) of rats given an intracerebroventricular infusion of oxytocin for 8 days. In a, the surface membranes of two soma profiles are seen to be in extensive apposition, that is, they are not separated by any neuropile or glial element (small arrows). Only a portion of the 15-µm-long apposition is shown in this micrograph. The oxytocinergic nature of the somata is revealed by colloidal gold particles (10 nm) over their secretory granules (see also insets), after immunostaining with a rabbit anti-oxytocin serum and immunoglobulin-coupled colloidal gold. In b, a presynaptic terminal (asterisk) synapses (between arrowheads) onto two adjacent soma profiles that are also juxtaposed (ap, attachment plaque bridging the apposed surface membranes). Colloidal gold particles (5 nm) over secretory granules in their cytoplasm identify the somata as oxytocinergic (see also inset). Scale bars, 0.5 µm; insets, 0.1 µm.

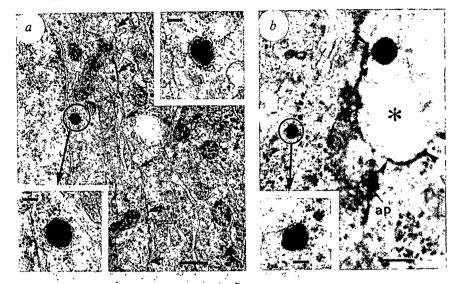

Fig. 2 a, Percentage of neurosecretory soma profiles showing neuronal appositions in the SON of rats after chronic (8 days) intracerebroventricular infusion of artificial cerebrospinal fluid (CSF), vasopressin (Vp) or oxytocin (Ox). This analysis was carried out without immunocytochemical identification of the neurones. Following infusion of oxytocin, nearly half of all the observed neurosecretory soma profiles were directly apposed to adjacent somata (S×S) or dendrites (S×D). b, Percentage of oxytocinergic and putative vasopressinergic soma profiles, identified immunocytochemically using anti-oxytocin serum, involved in S×S and S×D contacts in the SON of rats given intracerebroventricular infusions of oxytocin. In both histograms, numbers in parentheses represent the total number of soma profiles examined in each group. * P < 0.001, χ^2 analysis on raw data.

Methods. Two different quantitative analyses were carried out by two separate investigators, unaware of the experimental conditions. In the first (a), the analysis was performed on electron micrographs of neurosecretory soma profiles selected by a random sampling procedure (for further details see ref. 2); for each group, each composed of 5 animals, 128 micrographs were examined. In the second analysis (b), counting was performed directly at the electron microscope. In order to examine in detail larger areas of tissue surrounding each neurosecretory soma profile, all tissue falling within the whole surface of randomly chosen grid squares covering the whole frontal span of the SON was examined⁵. Four sections, each cut from different anterior-posterior levels of the SON of each of four animals that had been infused with oxytocin, were examined; the sections had been immunostained with a rabbit anti-oxytocin serum (preabsorbed with vasopressin adsorbed to CNBr-activated Sephadex beads) and immunoglobulin-coupled colloidal gold (a postembedding immunocytochemical procedure described fully elsewhere⁵). The same parameters were noted in each analysis: (1) total number of neurosecretory soma profiles; in the case of the immunostained SON, the peptide content of the somata was also noted (see Fig. 1); (2) number of soma profiles in juxtaposition to an adjacent soma or dendritic profile; (3) number of dendritic contacts per soma profile; and (4) number of 'double' synapses making contact with two neurosecretory soma or dendritic profiles simultaneously.

animals were deeply anaesthetized with sodium pentobarbital (50 mg per kg), and a cannula, connected to an Alzed miniosmotic pump (Scientific Marketing), delivering fluid at a rate of 0.5 µl h⁻¹, was inserted stereotaxically into the third ventricle. The pump was then left under the skin of the back at the level of the shoulders. The pumps contained synthetic oxytocin or vasopressin (Peninsula, 2 µg ml⁻¹ dissolved in artificial cerebrospinal fluid (CSF)), or artificial CSF alone. Eight days later, the animals were anaesthetized and perfused intracardially with heparinized saline followed by fixative (4% paraformaldehyde and 2.5% glutaraldehyde in 0.1 M sodium phosphate buffer). The brains were removed and 100-µm coronal slices were cut on a vibratome. The position of the cannula was verified on these sections. Each pump was emptied and the remaining fluid volume measured. The concentration of oxytocin and vasopressin remaining at the end of each infusion was measured by radioimmunoassay9. The biological activity of the remaining oxytocin was also tested by its potency to induce an increase in intrammamary pressure in mammary glands of lactating rats. Once it was ascertained that the cannula had been correctly

placed, and that the pumps had functioned properly, blocks containing the SON were dissected from the vibratome slices and processed further for electron microscopy (see ref. 5).

In the SON of animals infused with artificial CSF or vasopressin, as in nuclei from unstimulated animals (hydrated male^{2,10,11}, virgin female^{2,4} or post-weaned rats⁴), most neurosecretory soma profiles were separated from other neuronal profiles by glial or neuropile elements. On the other hand, in the SON of rats infused with oxytocin, glial coverage diminished markedly and close to 45% of all neurosecretory soma profiles were directly juxtaposed to adjacent soma or dendritic profiles (Figs. 1a, 2a). Moreover, the number of neuronal contacts more than doubled in this group, from 0.2 to 0.7 soma or dendritic contacts per soma profile. Concurrently, many of the same neurones (13%) were bridged by the same presynaptic terminal ('double' synapses; Fig. 1b), a type of synapse rarely seen in the nuclei of untreated animals $(<5\%^{2-4,11})$ or of animals infused with vasopressin or CSF (6%). In order to identify the neurones, a separate analysis was carried out on sections of the SON that had been immunostained for

oxytocin (Fig. 1a,b), using a post-embedding immunocytochemical procedure described in detail elsewhere⁵. This revealed that most of the soma profiles showing surface membrane appositions and sharing the same synapse after oxytocin infusion were oxytocinergic (Figs 1, 2b).

Our experiments demonstrate that a sustained elevated level of oxytocin in the third ventricle leads to morphological changes in the SON which are identical in nature and extent to those that occur under physiological^{2,4,5,11} or experimental^{10,11} conditions when the oxytocinergic system is activated. Our observations strongly suggest, therefore, that oxytocin does indeed take part in the restructuring of the hypothalamo-neurohypophysial system. Moreover, since infusion of the structurally similar neuropeptide vasopressin had no effect, it seems that oxytocin is specifically responsible for the anatomical changes.

Under normal conditions, oxytocin is present in the CSF¹² but its origin remains unclear. It may be released from oxytocincontaining neurones located in many areas of the CNS¹³. In particular, recent observations have described a local, calciumdependent release of this peptide from the magnocellular nuclei^{6,7}, and oxytocinergic terminals that are in contact with oxytocin cell bodies and dendrites have been noted in the SON8. Unlike the blood-brain interface, there is no barrier to the diffusion of oxytocin between the third ventricle and neighbouring cerebral structures¹². Our intracerebroventricular infusions of oxytocin would thus mimic an enhanced central release of oxytocin. The question then arises as to how a centrally circulating neuropeptide can induce anatomical changes in a particular

region of the CNS. Central oxytocin has been shown to increase the electrical activity of oxytocin neurones¹⁴ and the anatomical changes could be a consequence of such an activation. This possibility is supported by the observation that restructuring of the nuclei occurs under other situations, such as parturition³ and chronic dehydration^{10,11}, which also enhance the overall activity of oxytocinergic neurones¹. It is also possible, however, that oxytocin itself is the signal, acting on the surface membranes of oxytocin neurones, their synapses, or surrounding glia by an unknown mechanism.

The anti-oxytocin serum was generously provided by Dr A. Burlet. We also thank Mme A. Bonhomme for technical assistance and Mr S. Senon for photographic work.

Serine esterase in cytolytic T lymphocytes

Mark S. Pasternack*†‡, C. Reynold Verret*, Margaret A. Liu*† & Herman N. Eisen*

* Center for Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

Children's and ‡ Medical Services, Massachusetts General Hospital, Boston, Massachusetts 02114, USA and Departments of Medicine and Pediatrics, Harvard Medical School, Boston, Massachusetts 02115, USA

The mechanisms that enable cytotoxic T lymphocytes (Tc cells) to destroy target cells are only vaguely understood. However, recent studies have identified in T_c cells¹ and natural killer cells² cytoplasmic granules that contain perforin, a cytolytic protein that resembles the ninth component of complement (C9)3. Antigenspecific lysis of target cells, traditionally ascribed solely to T_c cells, has now also been demonstrated in some T-helper cell (Th cell) lines, referred to here as T helper-killer or T_{h/c} cells⁴⁻⁶. We recently found a novel serine esterase that is present at greatly elevated levels in cloned murine Tc cell lines and one Th/c cell line, but not in two non-cytolytic Th cell lines7. These findings suggest that the serine esterase is involved in cytolytic activity and that a variety of effector cells share a common cytolytic mechanism. To explore the role of the serine esterase in this process, we have been studying additional properties of the enzyme in murine T cells. We show here that (1) it is a membrane-associated, disulphidelinked dimer, (2) it has trypsin-like properties but is not a general protease, (3) in density gradient centrifugation it sediments with perforin, (4) it is secreted by Tc cells during their cytolytic attack on target cells, and (5) antiserum to Tc-cell serine esterase reacts with the enzyme in $T_{h/c}$ cells.

The serine esterase was isolated from T_c clone G4 cells as described in Fig. 1 legend, and the isolated protein was analysed by SDS-polyacrylamide gel electrophoresis (PAGE) under reducing and nonreducing conditions. Under both conditions the same complex was observed, but their apparent relative molecular mass (M_r) differed by a factor of about two (31,000-34,000 reduced and 55,000-60,000 nonreduced). Exactly the same difference in M_r was seen under these conditions when the enzyme was visualized by subjecting unfractionated cell lysates to affinity labelling with ³H-diisopropylphosphofluoridate (3H-DFP)7 and autoradiography (data not shown). It appears, therefore, that the enzyme is a disulphide-linked dimer. Whether its evident microheterogeneity reflects variable glycosylation or the presence of a few distinct but related ³H-DFPreactive serine esterases is not clear.

To determine whether all of the disulphide-linked subunits have DFP-reactive sites, the enzyme was examined under reducing conditions by two-dimensional PAGE (using non-equilibrium pH gradient electrophoresis (NEPHGE) in the first dimension)^{8,9}, visualizing the protein in some gels by silver stain¹⁰ (Fig. 1c) and in others by affinity labelling with ³H-DFP (Fig. 1d). In both cases, the appearance of the reduced protein was the same: a predominant component of $M_r \sim 31,000$ located close to the basic edge of the pH gradient with some heterogeneity evident in the form of a trail of slightly less basic protein of slightly higher M_r (32,000-34,000) (Fig. 1c, d). A single component, like that of Fig. 1c and d, was also seen following very brief NEPHGE electrophoresis (800 Vh. data not shown), indicating that another, more basic subunit had not been overlooked. Because the appearance of the reduced and nonreduced enzyme was the same when visualized by silver stain and ³H-DFP, both subunits in each dimer must be labelled by DFP, and have the same or very similar net positive charge; they are thus very similar and possibly identical.

To facilitate comparison of serine esterase in diverse clones of cytotoxic cells, rabbit antisera were raised against the purified enzyme (Fig. 1). The antisera immunoprecipitated only one ³Hlabelled component from ³H-DFP-treated lysates of G4 cells (data not shown) and they also reacted with the unlabelled lysates of cytolytic T cells by Western blotting (Fig. 2). In both assays the reactive material evidently corresponded to the serine esterase, as it was indistinguishable in M_r and appearance from the ³H-DFP affinity-labelled and silver-stained enzyme seen in Fig. 1 a, Purification of serine esterase from a clone of T_c cells, monitored by enzyme activity (absorbance at 412 nm) and by SDS-PAGE (insert), using silver impregnation to visualize protein. Insert: Lane A, the eluate from a lentil-lectin column (see Methods below) loaded on the lysine-Sepharose column; B-N, fractions from the lysine-Sepharose column; B, fraction 4; C, fraction 7; D, fraction 10; E, fraction 13; F, fraction 16; G, fraction 19; H, fraction 22; I, fraction 25; J, fraction 28; K, fraction 31; L, fraction 34; M, fraction 37; N, fraction 40; O, M, markers (×10⁻³). b-d, Some physical properties of the T-cell serine esterase. b, SDS-PAGE of purified esterase (pooled fractions 25-40, a) stained by silver impregnation. M, M, markers (top to bottom ×10⁻³): 90, 67, 45, 31 and 17. NR, nonreduced; R, reduced. c, Two-dimensional electrophoresis under reducing conditions of 5 μ g of purified serine esterase. The first dimension was non-equilibrium pH gradient electrophoresis (NEPHGE) and the second dimension was SDS-PAGE; protein was visualized by silver impregnation. d, Two-dimensional electrophoresis as in c of an Nonidet P-40 (NP40) extract of T_c cells (clone G4) labelled with 3 H-DFP. The DFP-rective protein was visualized by autoradiography of the slab gel.

Methods. $a_1 = 2 \times 10^9$ cells of T_c clone G4 (BALB.B anti-D^d, ref. 19) were suspended in lysis buffer (135 mM NaCl, 10 mM HEPES pH7.4, 3.5 mM MgCl₂) at ~10⁸ cells ml⁻¹ and disrupted by nitrogen cavitation (300 p.s.i. 15 min, 4 °C). Nuclei and whole cells were pelleted by centrifugation at 300g, 5 min. A wash of the pellet with lysis buffer was added to the post-nuclear supernatant, which was centrifuged at 100,000g for 1 h at 4 °C. The resulting supernatant (which had <1% of the initial esterase activity) was discarded and the pelleted membranes were suspended in 150 mM NaCl, 10 mM Na phosphate pH 7.4, 0.5% NP40 and 0.02% NaN3 (PBS/NP40) and loaded onto a lentil-lectin Sepharose column (Pharmacia) equilibrated in PBS/NP40 and washed with additional buffer. Approximately 60% of the activity was not retained and treatment of the pass-through with ³H-DFP revealed a single sharply defined band of M_r 31,000 on SDS-PAGE (not shown). The remaining 40% of estaerase activity, retained on the lentil-lectin column, was recovered by elution with 0.5 M α -methyl mannoside (α -MM) in PBS/NP40. After dialysing this eluate against 15 mM Tris-HCl pH 8.1, 0.02% NaN3, it was loaded (a, insert) onto a 5-ml lysyl-Sepharose column (Pharmacia) previously equilibrated with 15 mM Tris-HCl pH 8.1, 0.5% NP40, 0.02% NaN3 (TNA) and washed with this buffer. The column was monitored by assaying 1 µl of each fraction (~1.0 ml) for esterase activity, using benzyloxycarbonyl lysyl thioester (BLT) (Calbiochem) as described previously⁷. No esterase activity was detected in the pass-through. A NaCl gradient (0-500 mM in TNA) eluted the activity as a single peak, as shown, with the peak height at about 250 mM NaCl. For some preparations the column was equilibrated and washed with 1% octylglucoside in 15 mM Tris-HCl pH 8.1, before applying the NaCl gradient. Aliquots (20 µl) of fractions from the lysyl-Sepharose column were analysed under reducing conditions by electrophoresis in a 10% acrylamide gel in the presence of 0.1% SDS²⁰. After fixation of the slab gel in 50% methanol-10% acetic acid, the proteins were visualized by silver impregnation 25-40 were pooled. The serine esterase activity in the pool usually represented ~20% of the total initial activity and ~70% of the activity added to the lysine-Sepharose column. b, Purified esterase (~2.5 µg) was heated to 100 °C for 3 min in sample buffer not containing (NR) or containing (R) 5% 2-mercaptoethanol and analysed by electrophoresis in a 10% polyacrylamide gel in the presence of 0.1% SDS²⁰. Silver impregnation was performed as described elsewhere ¹⁰. c, Purified esterase (~5 µg) was dissolved in 25 µl of isoelectric focusing sample buffer containing 5% 2-mercaptoethanol, applied to a 4% polyacrylamide gel (2.5 mm × 12.5 mm) and electrophoresed under non-equilibrium conditions^{8,9} for 1,400 Vh. The gel was get (2.5 mm) and electrophoresed under non-equinorium conditions for 1,400 vn. The get was incubated with SDS sample buffer containing 5% 2-mercaptoethanol and layered on a 10% polyacrylamide slab gel and run in the presence of 0.1% SDS²⁰. Silver impregnation was performed as described elsewhere of d. An extract of 3×10° G4 cells in PBS containing 0.5% NP40 was treated with 10⁻⁵ M³H-DFP for 30 min at 37 °C and prepared for electrophoresis as described elsewhere. NEPHGE (1,300 Vh) and SDS-PAGE were performed as for b. The gel was impregnated with Autofluor (National Diagnostics, Somerville, New Jersey), dried and exposed for 8 days at -70 °C using XAR-5 film (Eastman Kodak).

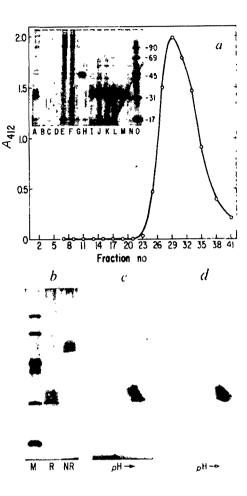

Fig. 2 Western blot analysis of cloned T_c , T_h and $T_{h/c}$ cell lines. Lane 1, purified scrine esterase (Fig. 1); lane 2, T_h cells (clone TDH-1); lane 3, $T_{h/c}$ cells (clone 5.5); lane 4, T_h cells (clone D10), lane 5, T_c cells (clone 2C); lane 6, normal thymocytes; lane 7, Con-A-activated thymocytes, lane 8, T_c cells (clone G4). M_r markers at the left are bovine serum albumin (67,000), ovalbumin (45,000), carbonic anhydrase (31,000).

Methods. Antiserum to the serine esterase was raised by injecting rabbits with $\sim 100 \,\mu g$ of purified enzyme (Fig. 1) in complete Freund's adjuvant and boosting them twice at 1-2-month intervals with the same amount of the enzyme in incomplete adjuvant. Cell extracts were prepared by washing cells several times in PBS and incubating them in 0.5% PBS/NP40 at 0 °C for 30 min with frequent vortexing. SDS was added to 0.1% and incubation was continued for another 15 min. After centrifuging the lysates at 8,000g for 10 min, supernatants (1-4 × 10⁶ cell-equivalents) were subjected to electrophoreis in SDS-10% polyacrylamide gels. Proteins were transferred electrophoretically from gels to nitrocellulose or Zeta-bind filters (A.M.F. Cuno) and, to reduce nonspecific binding in subsequent steps, the filters were incubated (1 h, room temperature) in 5% low-fat milk (Carnation) in PBS or in a 1:5 dilution of fetal calf serum in TBS (155 mM NaCl, 10 mM Tris-Cl pH 7.5) (TBS-FCS). The filters were then incubated for at least 3 h in anti-serine esterase antiserum diluted 250-fold in PBS-low fat milk or TBS-FCS, washed copiously with 0.05% Tween 80 in TBS, and finally treated sequentially with biotinylated anti-rabbit globulin and an avidin complex with biotinylated horseradish peroxidase, as described previously21 was developed with 4-chloro-1-naphthol and hydrogen peroxide as described elsewhere21. Clone TDH-1 is an L3T4⁺, 2,4,6 trinitrophenyl + H-2^d-specific clone of BALB/c origin; clone 5.5 is an L3T4+, ovalbumin+I-Ed-specific clone of BALB/c origin4; D10 is a conalbumin +1-specific clone of AKR origin⁵; clone 2C is BALB.B anti-L^{d'} (ref. 22); activated thymocytes were generated as described previously^{7,11}; G4 is described in Fig. 1 legend.

other gels (Fig. 1 and ref. 7). The Western blots (Fig. 2) showed the enzyme to be present at a high level in three cytolytic cell lines (two T_c and one $T_{h/c}$ cell line: 2C, G4 and 5.5, respectively) but to be undetectable in two non-cytolytic (T_h) cell lines (TDH-1 and D10). The antisera also detected the esterase in Western blots of murine thymocytes, providing these cells had been previously stimulated for 4 days in culture by concanavalin A (Con-A, Fig. 2, lanes 6, 7); these conditions induce the

expression of both cytotoxic¹¹ and serine esterase activity⁷. The antiserum to the enzyme from the T_c G4 cells reacted with enzyme in all of the other T_c clones tested and also in a $T_{h/c}$ -cell line. The slight variations in M_r values in different T-cell lines, and in the Con-A-activated thymocytes, suggest that there may be several related T-cell serine esterases or that a single enzyme is modified differently (for example, by glycosylation) in different T-cell lines.

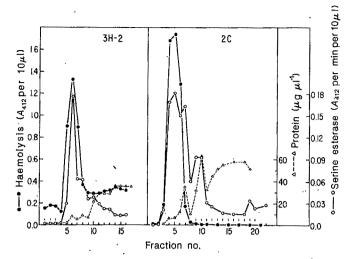

Fig. 3 Percoll-gradient fractionation of two cloned T_o-cell lines. a, Clone 3H2; b, clone 2C.

Methods. 5×108 3H2 cells (BALB.B anti-Dd, Lyt-2+, ree ref. 23) and 2.5×108 2C (ref. 22) cells were washed twice in Hank's balanced salt solution and once in 'relaxation' buffer (100 mM KCl, 3 mM NaCl, 3.5 mM MgCl₂, 1.25 mM EGTA, 1 mM ATP, 10 mM PIPES pH 6.8)²⁴. The cells were resuspended in relaxation buffer and lysed by nitrogen cavitation at 350 p.s.i. for 30 min. Nuclei and debris were removed by centrifugation at ~1,000 g for 5 min, and the supernatant was applied to a discontinuous gradient of Percoll in relaxation buffer (4 ml 90% Percoll, 2 ml 60%, 3.5 ml 39%) and subjected to centrifugation at 20,000 r.p.m. in a Beckman SW27 rotor for 30 min. Fractions containing ~0.8 ml were collected from the bottom of the tube with a peristaltic pump. Assay for haemolytic activity: The assay is a modification of Masson and Tschopp's procedure¹². Sheep erythrocytes were washed in HEPES buffered saline (HBS: 155 mM NaCl, 10 mM HEPES pH 7.3) and suspended at ~3×108 cells ml-1 in HBS containing 5 mM CaCl₂. Diluted or undiluted fractions (10 µl) were added to 100 µl of a sheep erythrocyte suspension. After 15 min at 37 °C, 1 ml of PBS containing 1 mM EGTA was added and the mixture was centrifuged at 1,500g for 5 min. Haemoglobin released in the supernatant was determined from the absorbance at 412 nM. Esterase activity was determined from plots of A_{412} against time. Protein was quantitated with the BCA protein assay reagent (Pierce) using bovine serum albumin standard. Percoll was removed after colour development by centrifugation at 8,000g for 5 min. Background due to Percoll and relaxation buffer was negligible.

All nine T_c cell lines tested showed markedly elevated enzyme levels: for example, $50\text{--}200\,\mathrm{U}$ per 10^6 cells⁷, corresponding at the upper limit to 1 μg trypsin-equivalents per 10^6 cells⁷. The enzyme level was also elevated in two $T_{h/c}$ -cell lines (clones 5.5 and 18) but not in four non-cytolytic T_h -cell lines (O_3 , O_5 (ref. 7), D10 and TDH-1). Although the presence of elevated serine esterase thus seems to correlate with cytolytic activity, many more murine T-cell lines, especially T_h and $T_{h/c}$ lines, will have to be examined to determine how consistently the correlation holds up.

The cytolytic protein perforin has been identified in cytoplasmic granules of human and mouse natural killer cells and mouse T_c -cell lines^{1,2}. By virtue of their high density, the granules can be separated from other cell lysate components and their isolation can be monitored by their lysis of sheep red blood cells. As Fig. 3 shows, the haemolytic and serine esterase activities sedimented together in T_c -cell lysates in dense fractions near the bottom of the Percoll gradient. This apparent association of the serine esterase with the cytolytic granules is supported by a recent analysis of M_r values of the reduced and nonreduced proteins isolated from the dense granules of a murine T_c -cell line¹² (compare our Fig. 1b with Fig. 2c in ref. 12) and by our unpublished observations that the ³H-DFP affinity-labelled pro-

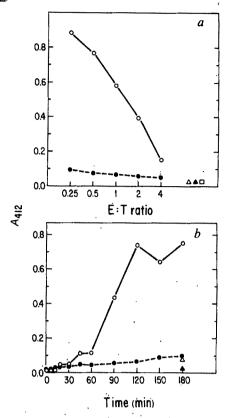

Fig. 4 Serine esterase secretion is triggered by cytolytic attack of T_c cells on specific target cells. a, Influence of the ratio of effector (T_c) cells to target cells (E:T ratio). b, Time course of serine esterase secretion. \bigcirc , Cells of T_c clone G4 (anti- D^d) incubated with P815 $(H-2^d)$ target cells; \blacksquare , G4 cells incubated EL-4 $(H-2^b)$ cells; \triangle , G4 cells incubated alone; \square , EL4 incubated alone.

Methods. G4 cells¹⁹ were collected, washed, resuspended at 5×10^5 cells ml⁻¹ in complete medium containing 20 U ml⁻¹ recombinant interleukin-2 and distributed into flat-bottomed microtitre wells (Costar 3596) at 105 cells per well. G4 cells readily attached to the plastic surface. After overnight incubation, the wells were gently aspirated and filled with cold KB1 medium (complete medium supplemented with bovine serum albumin (Boehringer Mannheim) at 1 mg ml⁻¹ in place of fetal calf serum). After several minutes on ice, the wells were aspirated again and to them were added (in triplicate) 100 µl medium alone or 100 µl medium containing varying numbers of P815 or EL-4 cells which had been washed two or three times in KBI medium and resuspended in KB1 at the designated concentration. The plates were incubated at 37,°C for 3 h in a or for the time noted in b. Samples (50 µl) were removed from replicate wells and pooled. Esterase activity in 10 µl of the pooled supernatants was measured as described elsewhere⁷. In a, E:T ratios were based on the nominal number of T_c cells seeded before the assay. Recovery experiments showed that no cell proliferation had occurred during overnight culture (data not shown). In b, the E:T ratio was held constant at 0.5 and plates were centrifuged briefly (500 r.p.m., 45 s) at 4 °C before initiation of the 37 °C incubation. The use of adherent T_c cells facilitated the detection and measurement of secreted esterase.

tein is present in the dense fractions that possess haemolytic activity (Fig. 3). Taken together, these findings strongly suggest that in murine T_c cells the serine esterase is present in the dense cytotoxic granules that contain perforin.

The serine esterase was previously shown⁷ to be blocked by DFP and phenylmethylsulphonyl fluoride, typical inhibitors of serine proteases. It is also blocked by aprotinin (data not shown), another typical inhibitor of trypsin-like serine proteases. However, the serine esterase did not cleave ¹²⁵I-casein (data not shown), suggesting that it may have restricted proteolytic specificity, as is characteristic of regulatory proteases¹³ (for

example, in some of the sequentially acting components of the complement 'cascade'). Whether the substrate for the serine esterase is perforin, or another component of the perforincontaining granules, or perhaps a surface protein of Tc or target cells remains to be be determined.

T_c cells normally lyse only cells whose surface antigens they recognize, not neighbouring cells that lack these antigens, suggesting that target cell lysis by T_c cells is not due to secretion of a diffusible cytotoxic molecule. However, when clone G4 cells were incubated with target cells, serine esterase activity appeared in the extracellular medium (Fig. 4). The enzyme released during lysis of the target cells remained in the supernatant after low-speed centrifugation (300 g, 5 min), sufficient to sediment intact cells, but was almost entirely (95%) sedimented following centrifugation at 100,000 g for 1 h. Under the latter conditions the purified enzyme (Fig. 1) is not sedimented, and thus the released enzyme was probably still largely associated with granule membranes or with another granule component, perhaps a proteoglycan^{14,15}. Enzyme release clearly accompanied the cytolytic attack on H-2d antigen-bearing target cells (P815), since it was not observed (Fig. 4) in various controls, for example, G4 cells alone or G4 cells incubated with cells possessing the wrong H-2 haplotype (EL-4 cells, H-2^b).

The amount of enzyme secreted varied with the ratio of effector (T_c) cells to target cells (E:T ratio). With an excess of target cells (low E:T ratio) the amount secreted was high, probably because under these conditions almost every T_c cell was likely to be interacting with a target cell; with a scarcity of target cells (high E:T ratios) the amount secreted was low, probably because under these conditions many Tc cells were not engaged with target cells (Fig. 4a).

The time course of secretion is shown in Fig. 4b. About twothirds of the amount present initially in the T_c cells was released. Whether enzyme biosynthesis keeps pace with secretion, or whether secretion results in sufficient depletion to reduce cytolytic activity ('killer cell exhaustion') are among the many issues that remain to be investigated. Target cell-triggered secretion of γ -interferon¹⁶ and interleukin-2 (ref. 17) from T_c cells has been observed previously. Comparison of the slow rate of secretion of γ -interferon¹⁸ with the far more rapid rate for the serine esterase suggests that the encounter of T_c with target cells induces the T_c cells to synthesize and then secrete γ interferon, whereas the same stimulus triggers the T_c cells to release their preformed serine esterase, contained in the cytolytic granules. Thus, in addition to their cytolytic effects the release of this enzyme and perhaps additional granule components by T_c and T_{h/c} cells might contribute to the slowly evolving local tissue injury known as delayed-type hypersensitivity.

We thank the following for providing cloned T-cell lines that have not yet been described in publications: David M. Kranz for T_{h/c} clone 18, Edward B. Reilly for T_c clone 3H2, and George Sigal for T_h clone TDH-1. We also thank Charles Janeway and John Tite for $T_{h/c}$ clone 5.5 and T_h clone D10, Robert D. Rosenberg and James Marcum for valuable discussions and purified casein, and Ann Hicks for preparation of this manuscript. This work was supported by research grants (CA-15472 and CA-28900) and a Cancer Center Core Grant (CA-14051) from the National Cancer Institute, NIH. C.R.V. is the recipient of a Massachusetts Institute of Technology Minority Fellowship Award and M.A.L. is the recipient of a Physician-Scientist Award frim the NIH.

Interferon response sequence potentiates activity of an enhancer in the promoter region of a mouse H-2 gene

Alain Israel, Akinori Kimura, Agnès Fournier*, Marc Fellous* & Philippe Kourilsky

Unité de Biologie Moléculaire du Gène, U277 INSERM, UA 535 CNRS and * Unité d'Immunogénétique Humaine, U276 INSERM, Institut Pasteur, 25 rue du Dr Roux, 75724 Paris Cedex 15, France

The expression of class I transplantation antigens encoded in the major histocompatibility complex (H-2 in mouse, HLA in man) can be induced by α -, β - and γ -interferons¹⁻⁵. Both transcriptional and post-transcriptional mechanisms have been postulated. Recently, a common sequence has been found in the promoter region of several human genes responsive to IFN- α (ref. 6). The promoters of $H-2K^b$ and several other mouse class I genes contain a similar interferon response sequence⁷. We show here, in a transient assay, that the $H-2K^b$ promoter can be induced by all three types of interferon and that the interferon response sequence is necessary for induction to occur. However, the response sequence is active only when associated with a functional enhancer sequence which we have recently identified in the promoter of $H-2K^b$ and other class I genes⁷. The combination of these two sequences can render a heterologous promoter responsive to interferon, irrespective of its orientation relative to the cap site.

We have previously noted the presence of an interferon response sequence (IRS) in the promoter of several H-2 class I genes⁷. In $H-2K^b$ and $H-2L^d$, the IRS overlaps with an enhancer⁷. To establish the role of IRS in the stimulation of class I gene expression by interferon (IFN), we have used a hybrid gene in which the bacterial chloramphenicol acetyltransferase (CAT) gene is fused to the $H-2K^b$ promoter⁸. This construct, called pH2CAT, has been transfected into mouse 3T6 cells. At 16-18 hours after transfection, the cells were treated, or not treated, with mouse type I IFN (100 U ml⁻¹) for 24 hours and CAT activity was assayed. In the same conditions, we confirmed by Northern blotting analysis that transcription of endogenous class I genes is stimulated two- to threefold by type I IFN (not shown). Results in Fig. 1a show that, in this transient assay, CAT activity is increased by IFN treatment. We then tested 5' deletion mutants of pH2CAT and found that dl393, which carries the IRS, responds to IFN, while dl122 and dl61, which do not have the IRS, are not stimulated (Fig. 1a). Similarly, the thymidine kinase (TK) and simian virus (SV40) early promoters in the constructs pTKCAT⁷ and pSV2CAT⁹ respectively were not stimulated (not shown). We analysed the

Fig. 1 a, Effect of type I IFN treatment on the activity of pH2CAT and 5' deletion mutants. A (-193 to -159) and B (-76 to -66) indicate the enhancer regions of the $H-2K^b$ promoter. I indicates the IFN response sequence (IRS:-165 to -137) which is closely homologous to the consensus sequence described by Friedman and Stark (see Table 1A). SE, stimulation effect. b, Effect of IFN treatment on the level of mRNA induced by pH2CAT and its 5' deletion mutants. Odd-numbered lanes: without IFN; even-numbered lanes: with IFN. Lanes 1, 2, dl122; lanes 3, 4, dl393; lanes 5, 6, pH2CAT; lane M, markers are pBR322 cut with HpaII and labelled with the Klenow enzyme. The sizes of the specific initiation (SI) and upstream initiation (UI) protected fragments are 283 and 344 nucleotides respectively.

Methods. a, Details of the construction of the plasmids and analysis of the enhancer activity have been described before⁷. Duplicate cultures of 3T6 cells (3×10^5) cells per 5-cm dish) were treated for 16-18 h with 0.5 ml of a 1.0-ml calcium phosphate co-precipitate containing 10 µg of plasmid DNA. The cells were then rinsed once and re-fed with fresh Dulbecco's modified Eagle's medium with 10% fetal calf serum with or without 100 U ml⁻¹ of type I IFN. Mouse type I IFN was a purified preparation (a mixture of IFN- α and - β) given by Drs I. Gresser and M. Tovey (specific activity 2.4×10^7 U mg⁻¹) and used in all experiments. A cytoplasmic extract was prepared 24 h later and CAT activity measured⁷. The protein concentration in the extract was measured with the BioRad protein assay. The ratio of the specific CAT activity (CAT activity/protein concentration) of cells treated with IFN to that of non-treated cells is shown as the stimulation effect (SE). The basal (unstimulated) levels of CAT activity were: 0.45, 1.45, 0.16 and 0.05 units per mg protein for pH2CAT, dl393, dl122 and dl61 respectively (1 unit represents 1 nanomol of chloramphenicol acetylated per h at 37 °C). These values are the results of both the deletions in the promoter and variable levels of upstream initiation. Experiments were performed at least five times and the average was obtained. Variations in stimulation effect between individual experiments never exceeded 20%. b, The steady-state level of CAT mRNA was measured by S, mapping analysis. The probe was a uniformly labelled EcoRI-HincII 600-bp fragment derived from dl61 and cloned in M13mp9; this fragment contains part of CAT gene, 75 bp of the K^b promoter (-63 to +12) and part of vector DNA. Using this probe, both SI and UI could be detected⁷. Total RNA was extracted 40 h after transfection from cells treated as described for a. To correct for variations in the efficiency of transfection, we included the plasmid pCH110¹⁹ in the transfection mixture and measured the β -galactosidase activity as described previously⁷. An average of 30 µg of RNA was hybridized with the probe for 16 h at 42 °C. Details for the probe, normalization of the quantity of RNA and S₁ mapping procedure have been described previously⁷.

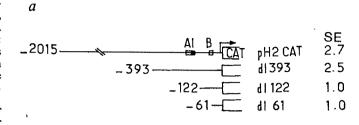

RNA transcripts by quantitative S_1 mapping experiments, with similar conclusions (Fig. 1b). It is important to note that transcription in pH2CAT and dl393 is stimulated from the authentic cap site of the $H-2K^b$ gene. However, nonspecific initiation from upstream site(s)⁷ located in the vector is also stimulated (Fig. 1b), as if the IRS would act as, or in conjunction with, an

Table 1 Stimulation by cloned human IFNs of $H-2K^b$ -derived constructs transfected into HeLa cells

	α	β	γ	A*	IRS*	в*
dl393	1.9	1.8	2.5	+	+	+
dl122	1.0	1.0	1.0			+
Dde-cII	2.8	3.1	3.9	+	+	
Dde-Hf	1.0	1.0	1.0	+		

HeLa cells were transfected as described for 3T6 cells (see Fig. 1 legend). IFN- α , - β or - γ were used at 200 units per ml of medium. The values given indicate the stimulation effect due to IFN and are the average of three experiments. The basal CAT values were similar to those obtained with 3T6 cells. Recombinant human IFN- α , - β and - γ have been produced by CHO cells transfected with the corresponding complementary DNAs, and purified by affinity chromatography 16-18. Their specific activities were respectively 2×10^8 U mg⁻¹, 5×10^8 U mg⁻¹ and 4×10^8 U mg⁻¹.

*These columns indicate the presence or absence in the construct of enhancer A, interferon response sequence (IRS) and enhancer B, respectively.

b

enhancer sequence. This observation prompted us to examine more closely the functional relationship between the IRS and the $H-2K^b$ enhancers.

We showed previously that two sequences derived from the $H-2K^b$ promoter, shown as A and B in Fig. 2a, display an enhancer-like activity when studied in the pconaCAT system⁷. Various fragments cloned in this vector were assayed for stimulation by IFN as described above and the results are shown in Fig. 2a. Stimulation is observed with the Sau3A-Sau3A fragment (which contains A, B and IRS) in both orientations, with the DdeI-HincII fragment (which contains A and IRS) but not with DdeI-HinfI (containing A alone) or HinfI-Sau3A (containing IRS and B). We conclude that both enhancer A and IRS are necessary for inducibility, and that they can act in both orientations on a heterologous promoter. Thus, IRS increases the activity of enhancer A upon IFN treatment. Not all enhancers can act jointly with IRS: enhancer B does not, nor does the SV40 enhancer which we cloned upstream of the HinfI-Sau3A fragment (Fig. 2a).

The Q10 gene¹⁰, which maps in the Qa region and is expressed specifically in the liver, also contains an IRS and an enhancer A-like sequence⁷. However, no stimulation by IFN can be observed with either the HinfI-HinfI (which contains the enhancer A-like sequence) or the HpaII-HaeIII (A-like sequence+IRS) fragment of the Q10 promoter cloned in pconaCAT (Fig. 2b). Both Q10 IRS and enhancer A-like sequence display some nucleotide differences from their homologues in $H-2K^b$ (Table 2A), and could thus be inactive. In fact, the Q10 enhancer

Part of the SV40 enhancer surrounding the core sequence¹⁵ and the consensus IRS⁶ are shown on the first line. Enhancer A of K^b is underlined in AI. The equivalent sequence and the IRS in the Q10 gene are underlined in BI. Lines II, III and IV show the nucleotides differing from line I in the different constructs indicated below. The + sign indicates positive response to IFN, while - denotes no effect (detailed in Figs 1-3).

A-like sequence is at least five times less active than the corresponding sequence of the K^b or L^d genes when assayed in 3T6 cells⁷. We constructed a hybrid Q10-CAT gene and derived two internal deletion mutants, pQ10CAT dl375 and dl167 (Fig. 3). We then built hybrid promoters by cloning enhancer A of the K^b , L^d or Q10 genes into pQ10CAT dl167 (Fig. 3). Neither deletion mutants respond to IFN, but the K^b and L^d sequences restore the responsiveness of the promoter to IFN treatment while Q10 enhancer A-like sequence does not (Fig. 3). In constructs which display IFN induction, specific as well as non-specific initiation is stimulated (confirmed by quantitative S_1

mapping analysis, data not shown), similar to results with the K^b promoter (Fig. 1b). Therefore, the IRS of the Q10 gene is potentially active, that is, it can also increase the activity of an enhancer A from K^b or L^d .

Some of these experiments have been repeated with a highly purified mouse IFN- γ preparation (kindly provided by Dr J. Wietzerbin), showing that the IRS sequence also responds to IFN- γ (data not shown). However, since the observed stimulations with mouse type I as well as IFN- γ were only two-to threefold, and since the type I IFN preparation which we used had not been purified to homogeneity, we wished to confirm

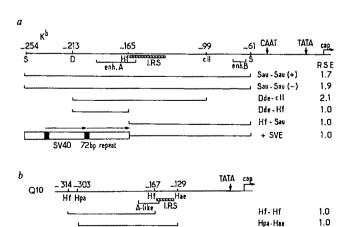

Fig. 2 a, Map of the promoter of $H-2K^b$ and various subfragments cloned in pconaCAT. S, Sau3A; D, DdeI; cII, HincII; Hf, HinfI; SVE, SV40 enhancer; Hpa, HpaII; Hae, HaeIII. RSE, relative stimulation effect. Orientation is indicated by arrows and the 'core sequence' by filled boxes. b, Map of Q10 promoter and subfragments cloned in pconaCAT.

Methods. Various fragments were cloned at the BamHI site (-102) of pconaCAT, in which the CAT gene is driven by the conalbumin promoter (-102 to +62)7, using BamHI linkers, except for the DdeI-HinfI fragment which was cloned by successive addition of HindIII and BamHI linkers. Further details for construction of pconaCAT and cloning of these subfragments are given in ref. 7. The 72-base-pair (bp) repeats of SV40 were derived from pSV23-2AgptΔLR (T. Kadesch, personal communication) as a 200-bp BamHI fragment (coordinates 273 to 95 in ref. 20) and cloned at the 5' BamHI site of the (HinfI-Sau3A) conaCAT construct. Transfection and enzyme assays were performed as described in Fig. 1a legend. Stimulation effect by IFN treatment for each plasmid is indicated as the relative stimulation effect (RSE), being compared with that for the pconaCAT construct, which does not respond significantly to IFN. The basal levels of CAT activity in a were 0.97, 0.45, 0.90, 2.2, 0.38 and 8.5 units per mg of protein for the Sau-Sau(+), Sau-Sau(-), Dde-cII, Dde-Hf, Hf-Sau and +SVE constructs, respectively. In b, the basal level of CAT activity was 0.38 units per mg protein for the two constructs.

Fig. 3 Map of the promoter of the Q10 gene and the Q10-CAT hybrid genes. Xba, XbaI; Bam, BamHI; HdIII, HindIII; (Hf), HinfI-HinfI fragment; (Dd), DdeI-HinfI fragment; IV, sequence identified in ref. 7 which corresponds to enhancer A for K^b or L^d , and to the enhancer A-like sequence for Q10. BL indicates the basal level relative to pQ10CAT dl167. The basal CAT activity of this construct was 0.2 units per mg protein.

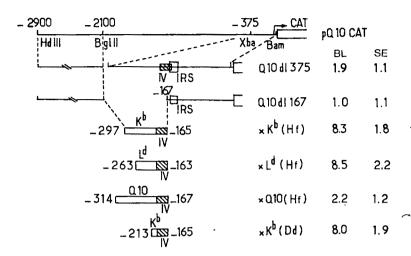

Methods. A HindIII-BamHI fragment (-2,839 to +14) of the Q10 gene (gene 8 in the cosmid library of Steinmetz et al.21) was isolated from cosmid 36.2 and cloned with HindIII linkers into pC α CAT²² between HindIII sites. This construct, named pQ10CAT, was linearized at the unique XbaI site and treated with Bal31 followed by digestion with BglII, treatment with Klenow polymerase and re-circularization, to construct internal deletion mutants (pQ10CAT dl375 and pQ10CAT dl167). The deletion end points were determined by sequencing analysis. A HinfI fragment which contains enhancer A of the $H-2K^b$ gene or its equivalent region in the $H-2L^d$ or Q10 gene as well as a DdeI-HinfI fragment derived from the $H-2K^b$ promoter (K^b (Dd); see Fig. 2a) were cloned in pO10CAT dl167 at the unique BglII site (-167) using successive addition of HindIII and BamHI linkers (to conserve the sequence of enhancer A 3' to the HinfI site except at one position, see Table 2). These fragments have been shown to have an enhancer activity when assayed in the pconaCAT vector system. A HinfI-HinfI fragment derived from the Q10 promoter has an enhancer activity about five times less than the K^b or L^d derived fragments \tilde{j} . The stimulation effect (SE) of IFN treatment was determined as described in Fig. 1a legend.

our results with recombinant IFN. Mouse recombinant IFN were not easily available to us. We therefore turned to human recombinant IFN. Since H-2 class I genes transfected into human cells can be regulated by human interferons¹¹, we decided to analyse the regulation of the $H-2K^b$ promoter in human HeLa cells, in response to recombinant human IFN- α , - β or - γ . Results in Table 1, obtained with the dl122, dl393, Dde-Hf and Dde-cII constructs, are similar to those obtained in 3T6 cells with mouse IFN, and demonstrate that all three IFNs stimulate the $H-2K^b$ promoter in a similar fashion. This strongly suggests that although the receptors for IFN- β and IFN- γ have been shown to be distinct¹², the final target on the $H-2K^b$ promoter is the same.

Our experiments with mouse type I IFN demonstrate that the IRS potentiates the action of a functional enhancer in the presence of IFN. This process is specific in the sense that the enhancer A needs to be functional, and that not all enhancers can be made responsive, as illustrated by enhancer B and the SV40 enhancer. The sequence arrangements of enhancer A and IRS in the various constructs described above are shown in Table 2. Interestingly, three mismatches in the enhancer A sequence (Table 2, compare AI and AIV, also BI and BII) are enough to abolish inducibility. Besides, as can be seen in Table 2 (compare AI and BI), enhancer A and IRS can be separated by several nucleotides and still respond to IFN. This suggests that the specific requirement for enhancer A may not be of topological nature. However, we cannot rule out the possibility that the SV40 and B enhancers could be potentiated at an appropriate distance. We have not shown that sequences located in the -137 to -99 region of $H-2K^b$ are irrelevant to IFN inducibility, but they are not conserved in the various IFN inducible genes⁶ and we did not find that they have any significant role in class I gene expression'.

This functional cooperation between an enhancer sequence and a second regulatory element is reminiscent of the response of the human metallothionin IIA (MTIIA) gene to heavy metals¹³. In the present case, the results could be interpreted in terms of a cooperative interaction between putative trans-acting factors binding to enhancer A and IRS.

Our results confirm that regulation of class I gene expression

by IFN- α , $-\beta$ and $-\gamma$ is, at least partly, transcriptional. We do not exclude additional post-transcriptional mechanisms, considering the relatively low degrees of induction observed and the findings of Yoshie et al.¹⁴ that an integrated truncated HLA gene, lacking the promoter region, still responds to IFN. Finally, it should be noted that, in the human MTIIA gene and in H-2and HLA class II genes, the IRS is located much further upstream from the cap site than in class I genes⁶. No homology with the class I enhancer A can be found in its vicinity. The mechanism by which these genes are regulated may then differ from class I genes. In this respect, it is noteworthy that maximum induction of the MTIIA gene requires 100 times more IFN-α than class I genes⁶.

We thank Drs I. Gresser and M. Tovey for the gift of type I IFN, Dr J. Wietzerbin for purified mouse IFN-γ, Dr D. Novick and Professor M. Revel for human IFN- α , - β , - γ , and Dr M. Steinmetz for making available to us the cosmid clone carrying the O10 gene. A.K. was a recipient of an IARC (WHO) fellowship, then a Foundation pour la Recherche Médicale Française fellowship.

Continuous and discontinuous protein antigenic determinants

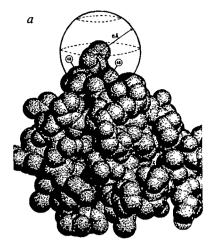

D. J. Barlow, M. S. Edwards & J. M. Thornton

Laboratory of Molecular Biology, Department of Crystallography, Birkbeck College, University of London, Malet Street, London WC1E 7HX, UK

Protein antigenic determinants have been classified as continuous or discontinuous 1,2. The continuous determinants are composed of residues which are local in the polypeptide sequence, while discontinuous determinants consist of residues from different parts of the sequence, brought together by the folding of the protein to its native structure. Searches made for protein determinants using peptide fragments which compete with protein-antibody complex formation, or peptides that can be used to raise antibodies which crossreact with the native protein, are limited to the simulation of continuous determinants. However, recent experiments^{2,3} suggest that most determinants are discontinuous. We now show, by consideration of protein surfaces, that if the recognition zone between a protein and antibody has the same dimensions as those found for the lysozyme-antibody complex⁴, none of the protein's surface will be 'continuous'. We suggest that all determinants are discontinuous to some extent, and that crossreacting peptides mimic only the 'primary' interaction site. In addition, we show that the parts of a protein's surface which are most continuous fall predominantly in the loops and/or protruding regions. This explains why quantities such as hydrophilicity⁵, accessibility⁶, mobility⁷ and protrusion⁸ can be used to predict which parts of a polypeptide provide the 'best' antigenic peptides.

The surface of a globular protein, as defined by X-ray crystallographic coordinates, is very complex and convoluted. However, visual inspection of any structure shows that most residues on the surface have neighbouring residues that are distant in the sequence. To quantify this observation, we have used the atomic coordinates available from the protein databank9 to search for 'continuous patches' on the surface of a protein. The method used (see Fig. 1a) involves centering a sphere of radius (r) on each surface atom in the protein, and calculating the proportion (F) of the other surface atoms enclosed by the sphere which belong to residues local in the amino-acid sequence. If a sphere encloses only local surface atoms, then we have identified a continuous patch. Surface atoms are defined as those with contact areas (calculated by the method of Lee and Richards¹⁰) >2Å²; local surface atoms are those belonging to residues in the sequence $i - n \rightarrow i + n$, where i is the residue containing the surface atom at the origin of a sphere, and n is an integer in the range 1-10.

When the percentage of surface atoms which lie at the centre of a continuous patch is plotted as a function of sphere radius, we obtain the surface 'continuo-grams' shown in Fig. 1b. Four separate plots are presented to show how the results depend on the definition for a local surface atom. These graphs are averaged over three proteins (myoglobin, trypsin and lysozyme), but the individual plots are essentially identical. Note that as the size of the sampling sphere increases, the percentage of the surface which is continuous decreases rapidly, until at a radius of ~10 Å virtually all of the surface is discontinuous, that is, there is no region of 20 Å diameter which contains only atoms from residues local in the amino-acid sequence. This relates directly to the observations made for the lysozyme-antibody complex, where the recognition zone is estimated to be 20 × 25 Å, and is discontinuous4. Note however, that this is a monoclonal antibody and has a reasonable affinity for its antigen; the association constant, K_A , is in the range $2-4\times10^7$ mol⁻¹ (R. Poljak, personal communication). Other antibodies that bind more weakly to their antigens may have smaller combining sites, which might there-

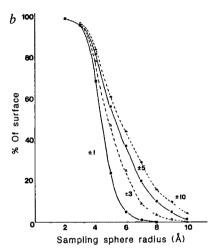

Fig. 1 a, Illustration of the method used to calculate the percentage of 'continuous surface' for a protein. The figure shows part of a space-filling model of lysozyme. A sampling sphere of radius 6 Å is centred on one of the surface atoms in the molecule: CG2 of Thr 47. The sphere encloses the atom centres of six other surface atoms, all of which are considered here as local surface atoms. since they belong to residues in the sequence 44-50. Two of the local surface atoms are labelled by residue number. Because all of the atoms enclosed by the sphere belong to local amino-acid residues, CG2 of Thr 47 is considered as the centre of a surface 'continuous patch'. b, Surface 'continuo-grams', showing the percentage of surface atoms which lie at the centre of a continuous patch as a function of sampling sphere radius. The four curves are obtained using different definitions for a local surface atom. (Specifically, these are atoms which belong to residues $i-1 \rightarrow i+1$, $i-3 \rightarrow i+3$, $i-5 \rightarrow i+5$, $i-10 \rightarrow i+10$, where i is the residue containing the surface atom at the origin of the sampling sphere.) Note that since the calculations (described in a and in the text) consider only atoms whose centres are enclosed by a sampling sphere, these curves represent conservative estimates of the percentage of continuous surface. If the intrusion of any fraction of an atom into the sampling sphere is considered, all of the curves will be shifted to the left.

fore be continuous. As we demonstrate below, however, this is not likely to be the case.

A low-affinity antibody, with $K_A = 10^4 \,\mathrm{mol}^{-1}$, will have a standard free energy of binding of $-6 \,\mathrm{kcal}\,\mathrm{mol}^{-1}$ (ref. 11). Assuming, therefore, that each Å² of the protein surface buried during association contributes 20 cal (ref. 12) to the binding energy, the buried area will be ~300 Å². Using sampling spheres of various sizes centred on each of the surface atoms in lysozyme, we calculate that this amount of the protein's surface area would typically involve a patch of ~8 Å radius. As shown in Fig. 1b, <10% of the surface patches of this size are continuous. Thus,

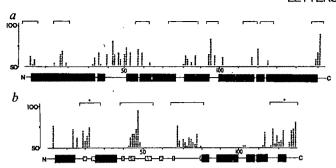

Fig. 2 Variation in $\langle F \rangle$ along the sequence of myoglobin (a) and lysozyme (b). (F) values for residues are plotted along the ordinate and the sequences of each protein along the abscissa. The locations of secondary structures in the proteins are shown below the corresponding plot; helices are represented by solid bars, \(\beta\)-strands by stippled bars and loop/turn regions by single lines. The locations of antigenic peptides¹³⁻¹⁵ are indicated above each plot; those labelled in b by • are discontinuous.

binding sites even for low-affinity antibodies are unlikely to involve only local amino-acid residues. We conclude that heptapeptides which cross react with protein antibodies mimic only part of the recognition area. Similarly, anti-peptide antibodies which recognize native protein will be limited to surface patches dominated by a short peptide, where interference from non-local residues is minimal.

On this basis, therefore, it would be reasonable to expect that the parts of a protein that are 'most continuous', should provide the best antigenic peptides. As Fig. 2 shows, this is indeed the case; the two plots illustrate the variation in $\langle F \rangle$ along the sequences of myoglobin and lysozyme, where $\langle F \rangle$ represents the mean value of F for all surface atoms in a residue, calculated using a sampling sphere radius of 10 Å (residues which do not contain surface atoms are assigned a value of $\langle F \rangle = 0$). The 'most continuous' patches in each protein are those where the residues have $\langle F \rangle > 50\%$. Note that there is a strong correlation between these regions and the location of antigenic peptides¹³⁻¹⁵.

An analysis of the surface compositions of 12 proteins shows that $\sim 50\%$ of all loop residues have $\langle F \rangle$ values > 50% (Fig. 3). The corresponding figures for helix and sheet residues are only 23% and 16%, respectively. As would be expected, therefore, most of the residues which form the most continuous regions lie in loops which protrude from the surface of the protein. Some are also found in helices, but none are found in the central strands of a β -sheet (where residues which are distant in the sequence will always be in close proximity).

These results provide a satisfying rationale, taken together with the necessity for antibody accessibilty⁶ or protrusion⁸, to explain which regions of a protein provide the 'best' antigenic peptides.

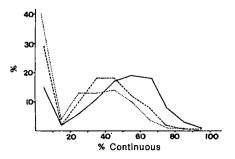

Fig. 3 The distribution of $\langle F \rangle$ values for residues in loop (helix (---) and β -strand (\cdots) regions. % Indicates the frequency of residues with an $\langle F \rangle$ value (% continuous) in a given

Expression of a transfected human c-mvc oncogene inhibits differentiation of a mouse erythroleukaemia cell line

Ethan Dmitrovsky*, W. Michael Kuehl*, Gregory F. Hollis*, Ilan R. Kirsch*, Timothy P. Bender* & Shoshana Segal*†

* NCI-Navy Medical Oncology Branch, National Cancer Institute, and † Department of Medicine, Uniformed Services University of the Health Sciences, National Navy Medical Center, Bethesda, Maryland 20814-2015, USA

The Friend-virus-derived mouse erythroleukaemia (MEL) cell lines represent transformed early erythroid precursors that can be induced to differentiate into more mature erythroid cells by a variety of agents including dimethyl sulphoxide (DMSO)2. There is a latent period of 12 hours after inducer is added, when 80-90% of the cells become irreversibly committed to the differentiation programme, undergoing several rounds of cell division before permanently ceasing to replicate^{3,4}. After DMSO induction, a biphasic decline in steady-state levels of c-myc^{5,6} and c-myb⁶ messenger RNAs occurs. Following the initial decrease in c-myc mRNA expression, the subsequent increase occurs in, and is restricted to, the G₁ phase of the cell cycle⁷. We sought to determine whether the down-regulation is a necessary step in chemically induced differentiation. Experiments reported here indicate that expression in MEL cells of a transfected human c-myc gene inhibits the terminal differentiation process.

To study the relationship between the down-regulation of the c-myc mRNA and cellular differentiation, a plasmid (PL¹hmcneo^r) containing the pSV2neo and the human c-myc genes was transfected into MEL cells (line 745). The stable G418-resistant transfectants (Fig. 1) were induced with DMSO to determine their differentiation potential. Strikingly, all transfectants which expressed the exogenous human c-myc gene failed to develop a red pellet or a positive reaction with benzidine after 7 days of induction. This inhibition of differentiation is not a transfection artefact. The parental MEL cells were subcloned after undergoing a sham transfection without selection, and all 24 subclones examined differentiated after 7 days of DMSO induction. In addition, transfectant T57, which expressed only the neomycin resistance gene, differentiated normally after induction. Introduction of another selection marker, the APRT (adenine phosphoribosyltransferase) gene, also does not interfere with induced differentiation of MEL cells8.

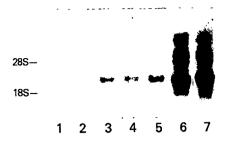

Fig. 1 RNA expression of the exogenous human c-myc in stable MEL transfectants. The inducible murine Friend-virus-derived1 erythroleukaemia cell line 745 (a gift from Dr J. Bilello) was transfected by a modified 16 calcium phosphate technique 17 with PL¹hmeneo' (a gift from Dr W. Lee). This plasmid is a derivative of the pCV108 vector¹8. It contains a 5.8-kb XhoI/EcoRI genomic human c-myc fragment (including all three c-myc exons) fused at the XhoI site of the first exon to a portion of the U3 and R of the Moloney murine leukaemia LTR. Total cellular RNA was prepared from the uninduced MEL parent and stable transfectants using the guanidine thiocyanate method previously described19. Total cellular RNA (10 µg per lane) was loaded, electrophoresed on a 1% agarose formaldehyde gel and blotted²⁰. The nitrocellulose filter was hybridized to a ³²P-dCTP nick-translated human c-myc 1.5-kb Cla1/EcoRI third exon probe overnight at 42 °C in a 10% dextran sulphate, 5×SSC, 40% formamide solution. After hybridization, the filter was washed for 1 hour at 60 °C with 0.1×SSC, 0.1% SDS and analysed by autoradiography using Kodak XRP.5 film and an overnight exposure with an intensifying screen. The five transfectants were obtained from three independent transfection experiments. The numbered lanes show the 745 MEL parent (lane 1), T57 (lane 2) T61 (lane 3), T62 (lane 4), T60 (lane 5), T56 (lane 6) and T55 (lane 7).

Two transfectants were selected for further studies to better define the effect of exogenous human c-myc expression on DMSO induction: T56, which expressed high levels of human c-myc mRNA, and T57 (Fig. 1). Both T56 and T57 were cloned by limiting dilution. Since the usual induction procedure (designated stationary phase induction) is limited by the 3-4 days taken for MEL cells to reach stationary growth^{2,3}, we modified this procedure to continue the induction longer. MEL cells were fed with enough medium (with or without DMSO) each day to maintain logarithmically growing cells at approximately the same density (designated logarithmic phase induction). Exponentially growing cells of clone 56 and 57 were seeded in medium without (control) or with (induced) DMSO. As shown (Fig. 2), clone 57, like the parental MEL cells, accumulated benzidine-positive cells to a maximum level of 90%. In contrast, cells from clone 56 were benzidine unreactive and the cell pellet remained white even after 14 days of induction. Another assay for terminal differentiation is clonability. Following DMSO induction, clone 57 rapidly lost its ability to generate subclones, while clone 56 showed no decrease in clonability after 14 days.

Steady-state levels of α -globin, c-myb and β -actin mRNAs, as well as exogenous human c-myc mRNA, were determined by Northern blots of total RNA prepared from clones 56 and 57 with or without DMSO (Fig. 3). The expression of β -actin was similar for the two clones, and remained essentially constant for control or induced cultures. Expression of exogenous human c-myc was stringently assayed so that the endogenous c-myc mRNA was not detected. As shown (Fig. 3), clone 56 expressed relatively high levels of two human c-myc mRNA species (approximately 2.3 and 2.1 kilobases (kb) in size). It is possible that transcription of these two mRNA species is initiated at the long terminal repeat (LTR) and P2 c-myc promoters, respectively. Notably, the expression of human c-myc mRNA decreased 6 hours after DMSO was added, and then declined more gradually during the next 10 days.

Using an α -globin cDNA probe, clone 57 expressed a basal level of α -globin mRNA which increased substantially during

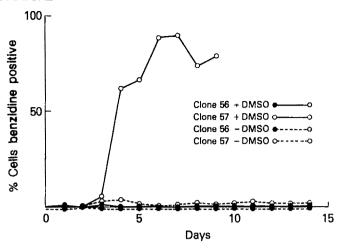

Fig. 2 Accumulation of benzidine-stained cells of clones 56 and 57 for uninduced and 'logarithmic-phase' induced cultures. Logarithmically growing cells of these clones were seeded at a density of 5×10^5 per ml on day -1 and split to 10^5 per ml one day later (day 0) in Joklik's modified medium supplemented with 75 µg ml⁻¹ of G418 (Geneticin, Gibco) and 10% fetal calf serum with or without 1.5% DMSO (Sigma). Each day half of the cells were removed from culture, harvested by centrifugation, washed twice with phosphate-buffered saline (PBS), and then stained for haemoglobin using the acid benzidine stain as previously described3. The remaining cells were replenished with an equal volume of fresh Joklik's modified medium containing G418 and 10% fetal calf serum, with or without 1.5% DMSO as indicated. For both the induced and uninduced cultures, 200 cells were daily assessed for benzidine reactivity and the percentage of benzidinepositive cells are provided for the indicated time points. The cell pellet of clone 57 became red approximately one day before the majority of individual benzidine-positive cells were seen.

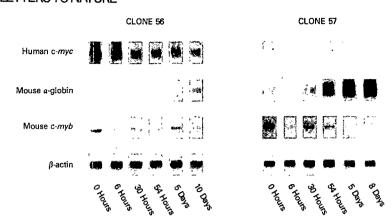

DMSO induction. This increase in α -globin mRNA expression was comparable in kinetics and magnitude to that observed with the parental 745 MEL line under stationary-phase induction conditions^{5,6}. In marked contrast, clone 56 expressed substantially lower basal levels of α -globin mRNA, which increased minimally after 10 days of induction. We do not know if this reflects low levels of expression in all cells or selective expression in a subpopulation of cells.

Changes in the expression of c-myb mRNA provide another marker for DMSO response. As expected, for clone 57 the changes in c-myb were indistinguishable from those previously observed for parental MEL cells (Fig. 3). For clone 56, the basal c-myb mRNA level was lower than for clone 57. This level of mRNA decreased within 6 hours after induction. Unlike the parental cells or clone 57, the level of c-myb mRNA stayed relatively constant during the remainder of the induction period.

To compare changes in expression of endogenous c-myc mRNA in the transfected cells, we used an S₁ nuclease protection assay to ensure that the endogenous mouse c-myc could be distinguished from the exogenous human c-myc expressed in clone 56 (Fig. 4). Despite the presence of high levels of exogenous c-myc mRNA, the endogenous c-myc mRNA continues to be expressed and the initial transient decline occurs although the second decline does not even after 10 days of induction.

The six parameters used to assess the response of clones 56 and 57 to DMSO induction were: cell pellet colour and benzidine staining of single cells; endogenous α -globin, c-myc and c-myb mRNA levels; and cell cloning efficiencies. These experiments clearly indicate a failure of clone 56 to differentiate normally, unlike clone 57 or the parental MEL cells. This inhibition occurs in five transfectants that expressed various levels of exogenous human c-myc mRNA (Fig. 1)¹⁰. These results are consistent with evidence from the avian myoblast cell culture system where myoblasts infected with retrovirus and expressing high levels of

Fig. 3 Expression of human c-myc, α -globin, c-myb and β-actin mRNAs in clones 56 and 57 during logarithmicphase induction by DMSO. Logarithmically growing cells of clones 56 and 57 were seeded, grown and harvested as described in Fig. 2. However, after washing in PBS, the removed cells were resuspended in guanidine thiocyanate for total cellular RNA analysis. Total RNA (10 µg) was applied to each lane, electrophoresed on a 1% agarose/formaldehyde gel and blotted²⁰. The obtained nitrocellulose filters were hybridized as described in Fig. 1 to the following probes: a, 1.5-kb ClaI/EcoRI third exon and 3' flanking human c-myc probe; b, 3-kb SstI fragment representing a murine α -globin cDNA prepared from a plasmid provided by Dr Y. Nishioka; c, 582 base pairs (bp) Smal/EcoRI murine c-myb cDNA fragment²¹; d, 1.9-kb BamHI fragment representing approximately full-length cDNA for human β -actin provided by Dr L. Kedes. The hybridized filters were then washed at 54 °C

as described in Fig. 1 except for filters hybridized to the ClaI/EcoRI human c-myc which were washed at 62 °C. Autoradiographs were obtained after exposure to XRP.5 film and an intensifying screen. Steady-state levels of the indicated mRNAs remained relatively constant for uninduced cultures. Densitometric analysis of Southern blots demonstrated 36 copies of the human c-myc gene integrated in the genome of clone 56 whereas clone 57 does not contain an intact human c-myc gene (data not shown).

v-myc protein fail to differentiate into myotubes¹¹. Recently, similar findings were reported in a thymidine kinase—MEL cell line where transfection of a simian virus 40—driven c-myc inhibits erythroleukaemic differentiation¹². Experiments to determine whether other oncogenes can substitute for this inhibitory effect are under way.

Some tumours can be induced to differentiate in culture. In many of these cases, the expression of the c-myc and c-myb oncogenes decreases during differentiation^{5,6,13-15}. Two patterns of decline have been observed. The first is a gradual disappearance of c-myc or c-myb mRNAs following induction of differentiation, as seen in the HL60¹³, WEHI3B¹⁴, and F9 cell lines¹⁵. The second is a biphasic decline in steady-state levels of c-myc^{5,6} and c-myb⁶ mRNA as seen in MEL cells. In general, malignant cells appear 'frozen' in a particular state of differentiation. Since qualitative or quantitative changes in oncogene expression are implicated as a cause of malignant transformation, it is possible that the apparent block in differentiation of tumour cells is due to abnormal oncogene expression. Our results suggest that c-myc expression plays a central role in determining whether a cell remains in a continuous cycle of growth and proliferation or enters a differentiation pathway.

We thank William Lee for use of the PL¹hmcneo^r plasmid,

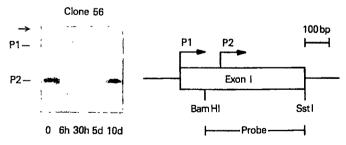

Fig. 4 Expression of endogenous c-myc mRNA determined by S₁-nuclease protection with clone 56 total cellular RNA obtained during logarithmic-phase induction (from the experiment described in Fig. 3). The single-stranded S₁ probe was prepared by primer extension of an M13 clone containing the 400-bp BamHI/SstI fragment derived from exon I of a genomic murine c-myc clone (obtained from Dr J. Battey). The probe was hybridized overnight at 55 °C to 10 µg of RNA using the previously described method²². After digestion with S₁-nuclease, the fragments were fractionated on an 8 M urea-5% polyacrylamide gel. The time points are hours (h) or days (d) after initiation of DMSO induction. The arrow indicates the position of the undigested probe. P1 and P2 represent promoters 1 and 2 of murine c-myc gene9.

James Battey for helpful discussions, and Virginia Bertness and Laura Minna for technical assistance.

DNA loops induced by cooperative binding of λ repressor

Jack Griffith, Ann Hochschild* & Mark Ptashne*

Lineberger Cancer Research Center, University of North Carolina Medical School, Chapel Hill, North Carolina 27514, USA * Department of Biochemistry and Molecular Biology, Harvard University, 7 Divinity Avenue, Cambridge, Massachussetts 02138, USA

It has been shown by Hochschild and Ptashne¹ that λ repressors bind cooperatively to operator sites separated by five or six turns of the helix. Cooperative binding is not observed if the sites are separated by a nonintegral number of turns, unless a four-nucleotide gap is introduced into one of the strands between the two sites. These and other facts suggested that repressors at the separated sites touch each other, the DNA bending smoothly so as to accommodate the protein-protein interaction. Here we use electron microscopy to visualize the predicted protein-DNA complexes.

Figure 1 shows the DNA molecules used in our experiments as well as the anticipated protein-DNA complexes. Fragments I and III bear two operator sites separated by five helical turns,

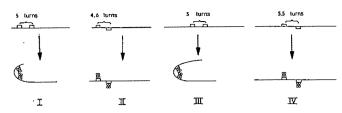

Fig. 1 DNA molecules used and expected shapes of complexes formed with λ repressor. The centre-to-centre distances separating the operator sites are given in helical turns and the molecules are drawn approximately to scale. DNA sequences spanning the two operator sites for each of these molecules are as previously described.

Table 1	Electron	microscopic	count of	DNA	fragments

DNA fragment	No. straight	No. bent	% Bent
1. I	36	8	19
2. I	50	32	39
3. II	213	0	0
4. II	37	0	0
5. II	32	0	0
6. II	46	1	2
7. III	113	9	7
8. III	67	7	9
9. IV	106	0	0
10. ÌV	86	0	0
11. IV	38	0	0

Each line represents a separate experiment. The repressor concentration in the first four experiments was one half that of the other experi-

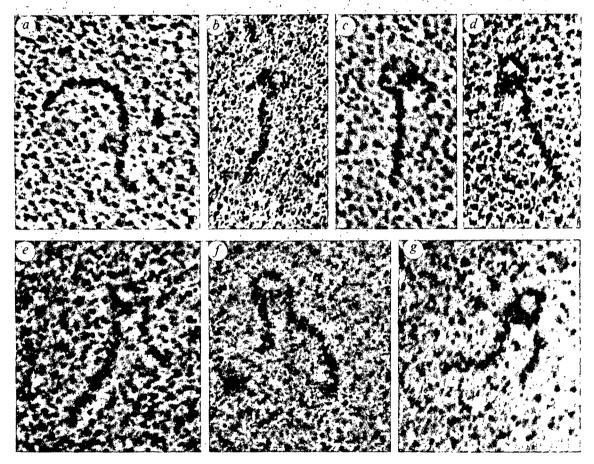

Fig. 2 Visualization of λ repressor bound to DNA fragments shown in Fig. 1. Purified λ repressor is shown bound to DNA fragments I (b-d), III (e-g) and II (a), as visualized by electron microscopy. In these experiments, 300-400 base-pair fragments containing repressor binding sites (20 ng ml⁻¹) were incubated with purified repressor (2 or 4 μg ml⁻¹) in a buffer containing 10 mM Tris-HCl, pH 7.0; 25 mM MgCl₂; 10 mM CaCl₂; 1 mM EDTA and 200 mM KCl. Supertwisted pBR322 DNA was included at 2 μg ml⁻¹ to reduce nonspecific protein binding. Following 20-min incubations at 37°, the complexes were fixed by the addition of HEPES buffer to 20 mM and formaldehyde to 1% for 5 min at 20°, followed by the addition of glutaraldehyde to 0.6% for an additional 5 min. The samples were directly mounted onto thin carbon films, washed with water and ethanol rinses, air dried and rotary shadowcast with tungsten as previously described¹⁰. Shadowcasting was done in a fully cryopumped system at a vacuum of 2×10⁻⁷ torr. The micrographs were taken with a Phillips EM400 instrument operated at 20 kv. Bar equals 0.1 μm.

assuming 10.5 base pairs per turn and measuring from the central base pair. The disposition of the two sites with respect to the ends of the molecule are different in the two cases and the protein-DNA complexes were expected to be distinguishable under the electron microscope. Fragments II and IV bear operator sites separated by 4.6 and 5.5 turns respectively and in this case we expected to see no looped DNA structures upon addition of repressor. In each case the two sites were those used previously¹. One is the wild-type site 0_R1 and the other a mutant

derivative $0_R 1^m$ that binds repressor sixfold more weakly than its wild-type parent. Experiments using DNase I to measure equilibrium binding show that repressor binds cooperatively to the separated sites on molecules I and III but non-cooperatively to the sites on molecules II and IV¹.

Figure 2 shows representative electron micrographs of protein-DNA complexes using three of our four DNA fragments. These samples were prepared by incubating repressor and DNA in conditions like those used to measure cooperative binding

using the DNase footprinting assay1. The samples were then fixed and shadowed with tungsten (see legend to Fig. 2). At the magnification required to visualize the short DNA fragments. two or more fragments were seldom found in the same field. Nonetheless it was not difficult to count and examine a statistically significant number of molecules for each sample. The DNA fragments were scored visually in the electron microscope as being either straight or bent with a small protein complex on the inside of the bend. Those that were scored as bent were photographed and subsequently examined to confirm this classification. Table 1 summarizes the distributions of molecules

Many examples of DNA fragment I were found in which the DNA was bent into a J shape with protein bound on the inside of the bend. (Fig. 2b-d; Table 1, lines 1 and 2). The loop between the bound repressors measured 15±5 nm, corresponding to 50 ± 15 base pairs. The location of the loop along the length of the 300-base-pair fragment and the length of the short arm (25 ± 5) base pairs) were consistent with the complex drawn in Fig. 1.

In contrast, only one in the 238 molecules of DNA fragment II examined appeared bent when repressor was complexed with this fragment (Fig. 2a; Table 1, lines 4-6). Repressor concentrations tenfold higher than those needed to produce looped structures with fragments I and III also failed to produce such structures (data not shown).

DNA fragments III and IV were prepared in Cambridge and sent to Chapel Hill labelled in code. Numerous bent complexes were found with one DNA sample (Fig. 2 e-g; Table 1, lines 7 and 8) but none with the other (Table 1, lines 9-11). As expected the former proved to be fragment III; the latter fragment IV. Note that the size of the loop observed with fragment III is similar to that observed with fragment I but that the shorter of the two arms emerging from the complex is approximately four times longer. This result is as predicted (see Fig. 1).

For all four fragments examined, it was common to observe what appeared to be a repressor on the DNA at one or the other binding site (see for example Fig. 2a). In most cases, the repressor appeared to be bound to the side of the DNA. As expected¹, there is no indication that the binding of a repressor to a single operator site bends the DNA. Very few fragments were found with two repressors bound, however, even though this was expected with fragments II and IV. It is possible that the fixation steps used here may have released many singly bound repressors from the DNA.

Several examples have now been reported of apparent protein-protein interactions "at a distance" that regulate gene expression²⁻⁸. Some if not all of these cases presumably involve formation of DNA loops^{2,3,9}. The electron micrographs described here provide the first direct visualization of loops formed when proteins bind cooperatively to separated sites on the DNA.

Length growth in fission yeast cells measured by two novel techniques

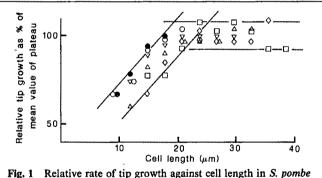

J. W. May* & J. M. Mitchison

Department of Zoology, University of Edinburgh, West Mains Road, Edinburgh EH9 3JT, UK

Time-lapse films have shown that cells of the fission yeast Schizosaccharomyces pombe exhibit a sharp increase in the rate of length growth at one stage of the cell cycle and that the same periodic increase in growth rate, a cell-cycle event, occurs in a cell-cycle mutant after the DNA division cycle has been blocked1. The continued periodicity of cell-cycle events after such a block has been shown in other systems^{2,3} and has intriguing implications for cell-cycle control models. We have therefore developed two new methods for measuring the rate of length growth which are equivalent to pulse labelling. The results confirm the evidence from films and also show that the rate of growth reaches a plateau after the blocked cells have achieved a critical size.

Time-lapse films are the most direct way of measuring cell growth, but analysis accurate enough for rate determinations is very time-consuming. In addition, some cell cycle mutants only grow under mounting conditions that prevent good optical resolution1. Our methods made use of the fact that Bandeiraea simplicifolia lectin (BSL) binds to the cell wall of S. pombe⁴. They also took account of the need to measure cell size as well as rate of growth, since the point where the rate changes in wild-type cells is size-related1. In our initial experiments with wild-type cells, an overall coating of BSL coupled to fluorescein isothiocyanate (FITC) was applied. The cells were then washed

cdc 2.33 at increasing times after shift-up to the restrictive temperature. Cells were grown up overnight at 28 °C in a minimal medium EMM3 (ref. 9) + 0.5% yeast extract + 0.1 µg ml⁻¹ biotin (this extra biotin was to guard against binding by traces of avidin). The medium was adjusted to pH 6.0 to promote lectin binding. The culture $(1.2 \times 10^6 \text{ cells ml}^{-1})$ was shifted to 36.5 °C at time zero. Samples were taken at 1 h (\bullet), 2 h (\bigcirc), 2.5 h (∇), 3 h (\triangle), 3.5 h (♦) and 4 h (□). Each sample was treated as follows: 1 min in biotinylated BSL (type BS 1) at 5 µg ml⁻¹; washed once; 1 min in avidin conjugated with Texas Red at 1.3 $\mu g \, ml^{-1}$ plus avidin at 5 μg ml⁻¹; washed twice; suspended in conditioned medium and incubated, one part (experimental) at 36.5 °C for 30 min and the other part (control) at 0 °C; then tip coating put on by 1 min in BSL-FITC at 2 µg ml⁻¹; washed once and preserved with formalin at 1%. Washing was done by centrifugation in a small bench centrifuge for 30 s at 13,400g. All reagents were from Sigma. Analysis was done in a FACS IV (Becton Dickinson) on 25,000 cells. The results were grouped for red fluorescence (length) and the peak value found for the green fluorescence (tip growth). There was appreciable penetration of the green lectin into the areas coated by the first red lectin. This was allowed for by taking the peak value of the green fluorescence in the control above (where there had been no tip growth) and subtracting this from the peak value of the experimental sample. The red fluorescence has been converted into cell length by taking the results from an earlier experiment in which cell length was measured against time after shift-up.

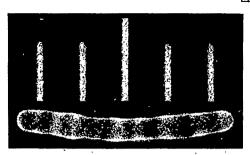

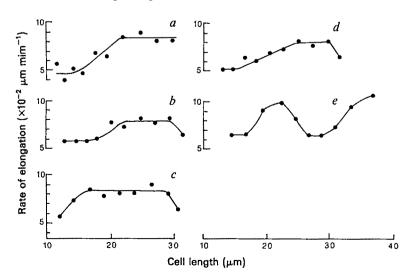

Fig. 2 A cell of S. pombe cdc 2.33 growing at both ends and coated alternately with lectin with FITC and lectin without FITC; a 'double-ended tiger-tail'. The coating procedure was as for Fig. 3 except that the intervals between coatings was 40 min. Scale divisions at 10-μm intervals.

and left to grow for 30 min (20% of the generation time). During this time, new uncoated wall was generated at the ends of the cell, as *S. pombe* grows by tip extension. At the end of the period, the new wall was coated with the same lectin but coupled with Texas Red through a biotin-avidin link. Under fluorescence microscopy, the cells were green with red tips. There was an intermediate yellow zone between body and tips due to overlap between the two lectins, and a mixing of old and new wall material at the growing tip.

Most of the experiments were done with a temperature-sensitive mutant of S. pombe cdc 2.33 (ref. 5). When the culture was shifted to the restrictive temperature (36.5 °C), mitosis was blocked but the cells continued to grow for several generation times and became very elongated. The coating procedure described above was used on cells of cdc 2.33 except that the sequence was reversed, with Texas Red being used as the body coating and FITC as the tip coating. This was done on samples taken every 30 min from 1 h after shift for 4 h. The samples were then analysed in a fluorescence-activated cell sorter (FACS) which measured each cell for red fluorescence (cell length minus tips) and green fluorescence (tip growth). The grouped results in Fig. 1 show that, as would be expected, the later samples had more large cells and fewer small cells. They also show that, irrespective of sampling time, the rate of tip growth increased with cell length up to a limiting length of about 20 µm. Thereafter the rate plateaued. These results are quite consistent with the rate changes observed in the time-lapse films since sharp steps in rate in individual cells would be spread out to give a slower rise in cell populations. What is missing is an initial rate plateau in the smallest cells before the rise. It proved impossible, however, to obtain reliable measurements of green fluorescence in these cells because they were contaminated by a subpopulation of small non-growing cells.

The second method used a coating procedure similar to the first one except that no fluorochrome was conjugated to the avidin. The important difference was that the procedure was continued for 6 h with alternate treatments every 30 min with lectin plus FITC and with lectin without a fluorochrome. The cells were photographed with a fluorescence microscope at the end of the experiment. They showed a pattern of bands (we call them 'tiger-tails') which define the history of length growth of each cell (Fig. 2). Analysis was by a ruler rather than a FACS. Growth appeared to be unaffected by the coating procedures, as we used short centrifugation times and worked in a warm room at 36 °C to avoid releasing the mutant block. Pulse times below 30 min were impracticable because the overlap mentioned above reduced contrast between the bands.

Cells which were small initially grew at one end and those which were large grew at both ends. The critical length was 11.5 µm at 1 h after shift-up. Double-enders were difficult to analyse, partly because many of them had a different number of bands at each end (see, for example, Fig. 2). Figure 3 therefore shows some representative graphs of the growth rate of singleenders. Of 32 cells analysed, 14 showed stepwise rises in rate (Fig. 3a,b). The mid-point of the step was at a mean of 18.3 µm (s.d. 2.36) and the mean increase in rate at the step was $\times 1.48$. This is in good accord with the results from films where the equivalent values were 19.4 µm and ×1.33. Other cells reached a plateau either with a very early step (Fig. 3c) or with a prolonged one (Fig. 3d). Taking these cells together with those with well-defined steps, 20 cells reached a plateau in rate at a mean length of 19.4 μ m (s.d. 3.1). This is very similar to the results in Fig. 1 from the FACS analysis. Nevertheless, there was a substantial minority of cells (14 out of 32) which did not fit these patterns and an extreme, though rare, example is shown in Fig. 3e. This variability in pattern (also found in the film results) is real and very probably greater in blocked mutants than in normal cells, but our results do emphasize the fact that analyses of whole populations can conceal what individual cells do. A final point about Fig. 3 is that three out of the five graphs show a fall in rate at the end, in contrast to Fig. 1. This is because the experiments were continued for 7 h, 2.5 h longer than in Fig. 1, and blocked mutants show a fall-off in rate after prolonged periods.

In conclusion, these two methods confirm the results from films¹ but by very different methods. The FACS analysis has also established a plateau in rate with longer cells. This was not previously known for cell length but has been shown for enzyme potential⁶ and for the rate of synthesis of protein⁷ and ribosomal RNAd⁸. We believe that the methods should have wider application in other cells which have rigid cell walls and defined growing points.

This work was supported by the SERC and the Cancer

Fig. 3 Representative patterns for rate of tip growth against cell length in individual cells of S. pombe cdc 2.33 for 7 h after shift-up. Cell growth, medium and shift-up were as for Fig. 1. Cells were taken at 1 h after shift-up; treated for 1 min in biotinylated BSL at 5 μg ml⁻¹; washed once; 1 min in avidin at 5 μg ml⁻¹; washed twice; resuspended in conditioned medium and incubated at 36.5 °C for 30 min; then treated for 1 min in BSL-FITC at 2 μg ml⁻¹; washed once; incubated for 30 min and the BSL-biotin-avidin coating repeated. The cycle of alternate avidin-biotin and FITC coatings was repeated every 30 min until 7 h after shift-up. The cells were finally fixed in 1% formalin and photographed in a Zeiss Photomicroscope I with a ×40 objective and the exciting wavelength for FITC. The band positions were measured on photographic enlargements.

Research Campaign. We thank Drs J. Creanor, P. A. Fantes and R. A. Gray and Mr A. B. Sanderson for assistance in some experiments and for helpful discussions.

Propulsion of organelles isolated from Acanthamoeba along actin filaments by myosin-I

Richard J. Adams & Thomas D. Pollard

Department of Cell Biology and Anatomy, Johns Hopkins University School of Medicine, 725 North Wolfe Street, Baltimore, Maryland 21205, USA

Eukaryotic cells are dependent on their ability to translocate membraneous elements about the cytoplasm. In many cells long translocations of organelles are associated with microtubules 1-3 In other cases, such as the rapid cytoplasmic streaming in some algae, organelles appear to be propelled along actin filaments⁴. It has been assumed, but not proven, that myosin produces these movements. We have tested vesicles from another eukaryotic cell for their ability to move on the exposed actin bundles of Nitella⁵ as an indiction that actin-based organelle movements may be a general property of cells. We found that organelles from Acanthamoeba castellanii can move along Nitella actin filaments. Here, we report two different experiments indicating that the singleheaded non-polymerizable myosin isozyme myosin-I (ref. 6) is responsible for this organelle motility. First, monoclonal antibodies to myosin-I inhibit movement, but antibodies that inhibit double-headed myosin-II do not. Second, ~20% of the myosin-I in homogenates co-migrates with motile vesicles during Percoll density-gradient ultracentrifugation. This is the first indication of a role for myosin-I within the cell and supports the suggestion of Albanesi et al.7 that myosin-I moves vesicles in this way.

We saw directed motion of vesicles and aggregates of vesicles from Acanthamoeba on the substrate of Nitella actin bundles (Fig. 1). Movements were in the same direction as those of endogeneous algal organelles but substantially slower (Fig. 2b),

the average rates of movement being $0.24 \pm 0.11 \,\mu\text{m s}^{-1}$ (mean \pm s.d., n = 50) compared with $\ge 40 \,\mu\text{m} \text{ s}^{-1}$ for endogeneous movements8. The distribution of rates of movement for Acanthamoeba vesicles was wide (Fig. 2b) and varied from batch to batch. The vesicles in some preparations were never seen to move; the cause of this variation is unknown. Further, in any one extract, not all of the vesicles that settle onto the substrate were seen to move. We could follow moving vesicles for tens or hundreds of micrometres; the data in Fig. 2 represent the average rate measured over a distance of 20-140 µm. Rates of motion were relatively constant over these distances without the saltations or interruptions characteristic of oganelle movements within live cells. Most of the movements that ceased in the field of view appeared to result either from damage in the substrate or from steric interference. We are confident that the movements of Acanthamoeba vesicles is independent of those of Nitella organelles for several reasons: no endogeneous organelles are seen to move with this speed and all that show any signs of movement are lost from the preparation soon after dissection. (Experiments were not performed on dissected Nitella preparations while endogeneous organelles were still moving.) To check this, two preparations of dissected Nitella were incubated in 5 mM N-ethylmaleimide for 5 min to inhibit the activity of the endogeneous myosin species⁹. After treatment with 7 mM dithiothrietol to neutralize the N-ethylmaleimide, no endogeneous organelles moved but organelles in Acanthamoeba extracts moved normally. The enzyme responsible for their motion would, therefore, appear to be associated with the vesicles themselves.

Acanthamoeba contains two distinct species of myosin^{6,10,11} which are candidates for the motor driving of these vesicles along the actin bundles of the Nitella cortex. The two species differ, both physically and enzymatically: myosin-I is enzymatically highly active⁶ but, unlike Acanthamoeba myosin-II and other known myosins, it consists of only one heavy chain which lacks the long α -helical tail required for polymerization into thick filaments^{6,7}. Like most other myosins, myosin-II has two heads and a tail and can form bipolar filaments.

We used monoclonal antibodies to show that myosin-I but not myosin-II is required for organelle movements along actin filaments. Antibody M1.5 inhibits stochiometrically the actinactivated ATPase of myosin-I (ref. 12) and antibodies M2.3, M2.10 and M2.26 all stoichiometrically inhibit the actin-activated ATPase of purified myosin-II as well as the contraction of actin gels in crude cytoplasmic extracts¹³. These four antibodies react with the heavy chains of either myosin-I (M1.5) or myosin-II (M2.3, M2.10 and M2.26) among the various proteins in cellular extracts^{12,14}. M1.5 and other monoclonal antibodies to myosin-I also bind to nuclear proteins¹². In blind experiments antibody M1.5 completely stopped all organelle movement on

Fig. 1 a. Organelles (arrows) moving on a substrate of Nitella actin bundles, photographed at 15-s intervals. The image-processing procedure (see below) causes the image of the organelles to change from frame to frame. Photographs prepared from moving organelles recorded on videotape. Scale bar, 10 µm. Actin bundles oriented horizontally. b, Phagocytic vesicles rendered visible by feeding the cells fluorescent beads before homogenization. Fluorescent organelles (arrows) are seen against the autofluorescence of the Nitella chloroplasts. Photographs taken at 30-s intervals from an unprocessed video-recording. Scale bar, 10 µm. Actin bundles oriented horizontally.

Methods. Acanthamoeba castellanii were grown in liquid culture as described previously6. Organelles were prepared freshly each day starting from approximately 0.2 g wet weight of compacted cells, washed three times in 50 mM NaCl. The cells were resuspended in 1 ml of homogenization buffer (60 mM potassium glutamate, 2 mM EGTA, 2 mM MgCl₂, 10 mM imidazole pH 6.4, 0.1 mM benzamidine, 1 mM phenylmethylsulphonyl fluoride and 4 mM ATP) and disrupted by eight strokes with a tight-fitting pestle in a 7-ml Dounce homogenizer. The homogenate was cleared of unbroken cells and large particles with a 5-s spin at 10,000 g in a bench-top Eppendorf centrifuge. The resulting supernatant was used for all the experiments. In some experiments cells were preprared with fluorescent phagocytic vesicles. Washed cells were incubated, with occasional mixing, for 15 min at room temperature in a dense suspension of rhodaminelabelled polyacrolein beads in 50 mM NaCl. (Beads of $\sim 0.5 \,\mu m$ diameter were prepared by

the method of Margel et al.²³). Labelled cells were further washed three times in cold saline and processed as before. Nitella was dissected as described by Sheetz and Spudich' in a buffer of 20 mM KCl, 4 mM EGTA, 4 mM MgCl₂, 10 mM sucrose, 5 mM imidazole pH 7.0 and 2 mM ATP. The suspension of organelles was mixed 1:1 with homogenization buffer containing 0.2 M sucrose and added to a region of exposed Nitella ectoplasm with a microcapillary. Motion of organelles on Nitella was observed on an upright Zeiss microscope with a ×40 water-immersion, phase-contrast objective. At this magnification movements were too slow to be discerned by eye but became obvious when speeded up by time-lapse video microscopy. The microscope was fitted with Dage-MIT Newvicon video camera, the output of which was passed through a Quantex digital image processor (DS 30) and Colorado Video analogue video processor (604) before being recorded at 1/18 real-time on a National Panasonic (NV 8030) time-lapse video recorder. Detection of movement of small vesicles on the complex substrate was difficult, so the following image-processing regime was used to selectively enhance moving particles. The image processor continuously subtracted an image of the non-moving Nitella background from the incoming picture. Thus, only differences between the two images are seen, that is, objects that moved. This technique is complicated because the Nitella substrate distorts to some extent during the experiment (~20 min). To overcome this, the background image was itself slowly averaged using a rolling average, with the incoming image, that replaces the stored image every 128 frames. It is necessary to ensure that the rate of averaging is slower than the rate of detection of the differences (the rate of recording on the video recorder). The contrast of the difference image from the digital processor was further enhanced with the Colorado Video analog processor.

Nitella actin bundles, whereas antibody inhibitors of myosin-II (M2.3, M2.10 and M2.26) had no obvious effect on organelle movements (Fig. 2a). The average rate of movement was $0.23 \pm 0.09 \,\mu\text{m s}^{-1}$ (mean $\pm \text{s.d.}$, n=12) in the presence of myosin-II antibodies. A ratio of M1.5 antigen binding sites (this antibody is an immunoglobulin M) to estimated myosin-I content of the extract (1.3 μ mol per kg of wet cells⁶) of 20:1 reproducibly inhibited motion whereas a ratio of 2:1 inhibited motion in one but not a second of two sets of experiments. Ratios of 0.2:1 or 0.02:1 did not inhibit movement (Table 1). These experiments provide evidence that the movement of the organelles is driven by the smaller myosin species, myosin-I. The rate of motion of these organelles is ~10 times higher than that recently reported for plastic beads coated with myosin-I on a Nitella preparation⁷.

The composition of the homogenate used for these experiments is highly heterogeneous so we do not yet know which organelles are moving. But by pre-labelling phagocytic vesicles of the cells with fluorescent beads we could show that these were among the organelles that move in our experiments (Fig. 1b). This could be a subset of the total moving population.

We used cell fractionation to test whether myosin-I is physically associated with the motile vesicles (Fig. 3). When the crude extracts used in the motility experiments were centrifuged on a Percoll gradient, organelles sedimented into the density gradient and were separated from the soluble components at the top of the tube. Organelles that came to equilibrium at a density of 1.08-1.13 g ml⁻¹ were motile on *Nitella* actin bundles. This fraction was also greatly enriched in myosin-I relative to myosin-II, which remains essentially in the supernatant. Approximately 20% of the myosin-I in the extract sedimented with these motile organelles. Tests with specific monoclonal antibodies¹⁰ showed that both myosin-IA and -IB are associated with organelles. Therefore, there is a stable interaction of myosin-IA and -IB with organelles that persists through centrifugation, is insensitive to ATP and is competent to move organelles along actin bundles.

These experiments show that an actomyosin system can provide the force for some membrane movements within the cell, as has been speculated based on experiments with myosin-coated beads⁵⁻⁷. The heterogeneity of the organelles in our preparation and the fact that we used a cell-free system do not

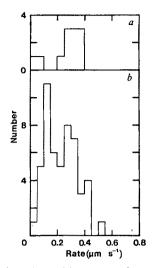

Fig. 2 Distribution of velocities of Acanthamoeba vesicles on a Nitella actin bundle substrate. a, Movement of 12 organelles in the presence of antibodies to myosin-II; b, accumulated results from 50 organelles measured in control preparations.

Methods. The net speed of movement for a vesicle was measured from the replay of a videotape recording of an experiment. The positions at the beginning and end of a timed motion were marked on the video monitor. The screen coordinates of these two points were read using a Colorado Video analyser (321) and the corresponding displacement calculated with account being made of lateral distortions introduced by the video camera. Speeds were recorded for displacements of 20-140 µm.

yet permit us to identify directly the nature or role of these movements in the cell. Immunofluorescent localization of myosin-I in the cell^{12,15} reveals a cortical concentration which suggests an involvement of myosin-I-powered movements in endocytosis or surface movements in addition to organelle movements. Such processes may be important in other cells since myosin-I has now been indentified in Dictyostelium¹⁶ and a

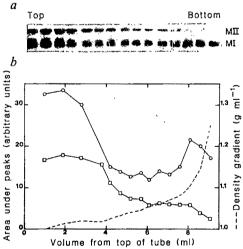

Fig. 3 Acanthamoeba cytoplasmic extract (0.5 ml) was layered onto 9.0 ml of 1.08 g ml^{-1} Percoll in homogenization buffer and centrifuged at 27,000 r.p.m. in a Beckman Ti 50 rotor for 15 min. The gradient was unloaded from the bottom of the tube; the densities of Percoll in the collected fractions was determined from refractive indices. Aliquots of these fractions were electrophoresed on 7.5% gels²⁴, transferred to nitrocellulose²⁵ and radioimmunologically stained with antibodies to myosin-I and -II (a). The autoradiogram shown in a was scanned using a soft-scanning laser densitometer to show the distribution of the antigens in the fractions collected from the gradient. MI, myosin-I; MII, myosin-II. b. Relative areas scanned under the peaks of myosin-I and -II were plotted for each fraction through the gradient. Circles, myosin-I; squares, myosin-II.

similar ATPase has been identified as the link between the actin filaments and the membrane in microvilli¹⁷. Previous results which suggested a possible role for actin filaments in organelle movements in other cell types^{1,18-22} may also be mediated by proteins like myosin-I.

Lateral proton conduction at lipid-water interfaces and its implications for the chemiosmotic-coupling hypothesis

Michel Prats, Justin Teissié & Jean-François Tocanne*

Centre de Recherche de Biochimie et de Génétique Cellulaires du CNRS, 118 Route de Narbonne, 31062 Toulouse Cédex, France

The driving force in energy-transducing membranes is now recognized to be linked to a flux of protons between membrane-bound donors and acceptors. The question of whether the proton pathway is delocalized within the two bulk aqueous phases on each side of the membrane (delocalized chemiosmotic theory1), or is localized at its surface (semi-localized hypothesis2) still remains open to discussion^{3,4}. Using an original fluorescence monolayer technique, we have recently been able to provide direct experimental evidence that a phospholipid-water interface can act as an efficient proton conductor^{5,6}. This observation strongly supports the semi-localized hypothesis². In the present study, comparisons between surface potential and fluorescence measurements in monolayers provide additional evidence of a facilitated proton conduction along phospholipid-water interfaces. They suggest the existence of an induced steep surface pH gradient from a more acidic surface towards the bulk. They also show that lateral proton transfer along the surface of a biological membrane would alter the surface potential of that membrane.

The surface potential ΔV which is measured for lipids in monolayers is known to originate primarily from the polar headgroups and to depend on their ionization state⁷. Therefore, since the lipid is the probe itself, this technique affords an elegant way of observing the lateral movements of protons and of

^{*} To whom correspondence should be addressed.

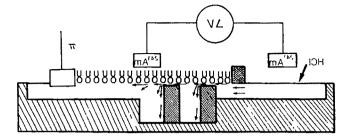

Fig. 1 Schematic drawing of the experimental set-up. The monolayer experiments were carried out with the same trough and using the same experimental conditions as previously described for fluorescence experiments^{5,6}. The trough comprised one 'injection' and one 'observation' compartment separated by two glass barriers. Continuity of the subphase occurred via a very thin water layer, about 1 mm in depth, between the water surface and the top of the barriers. π was measured by means of a platinum plate connected to a force transducer of our own manufacture. Surface potential was measured by two americium electrodes¹¹. One (reference) was located above the lipid-free region of the 'injection' compartment. The other (measurement) faced the lipid film. The 'standard' conditions^{5,6} we used were: the 'measurement' electrode was centred at a distance of 4.3 cm from the first glass barrier; the area of the monolayer in direct contact with the acidic subphase in the 'injection' compartment was 12.6 cm²; protons (150 µl 3 M HCl) were injected under stirring (Teflon bar, 90 r.p.m.). 'Standard' conditions of subphase (1 mM phosphate, pH 6.8) and film surface pressure (25 mN m⁻¹) were used. Arrows indicate the various diffusion pathways of protons which can move along the lipid/water interface and which can also diffuse through the bulk of the water phase by a combination of diffusion and convection movements.

determining to what extent the polar headgroups are involved in the proton conduction process.

Three phospholipids were examined: phosphatidy-lethanolamine (PE) from Escherichia coli (Sigma), phosphatidylserine (PS) from bovine brain (Sigma) and dilauroylphosphatidylglycerol (PG) of synthetic origin⁸. As shown in Fig. 1, the trough, the method for generating the flux of protons and the experimental conditions used were identical to those previously described for the fluorescence experiments^{5,6}.

Typical ΔV recordings with time are shown in Fig. 2. Less than 3 min after proton injection, a large increase in ΔV was observed for each lipid. A positive change in ΔV is expected if protons concentrate at the lipid-water interface⁷. From these curves, two parameters were determined: (1) $TH_{\Delta V}^{+}$, the time which is necessary to detect a change in the surface potential and which relies on the rate of proton transfer along the lipid/water interface^{5,6}, (2) $\Delta \Delta V$, the change in surface potential which, like the change in surface fluorescence ΔF (refs 5, 6), accounts for the variation in proton concentration at the interface. $TH_{\Delta V}^{+}$ and $\Delta \Delta V$ values measured for each lipid are shown in Table 1.

Fluorescence investigation of proton conduction by phosphatidylserine and phosphatidylglycerol was carried out exactly as previously described for phosphatidylethanolamine^{5,6}. 'Standard' conditions of subphase (1 mM phosphate, pH 6.8) and

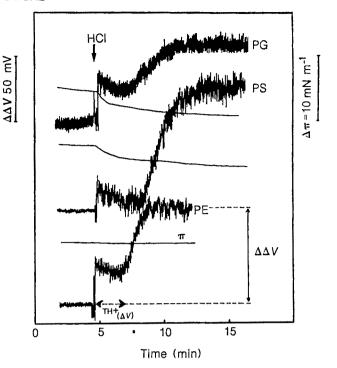

Fig. 2 Kinetics of the surface potential and surface pressure changes after an acid jump. Phosphatidylglycerol (PG), phosphatidylserine (PS) and phosphatidylethanolamine (PE) were spread at a surface pressure of 25 mN m⁻¹ by stepwise deposition of the lipids onto the subphase. The left part of the curves refers to the surface potential which was initially measured after spreading the lipids on the 1 mM phosphate subphase at pH 6.8. Addition of HCl gave rise to an immediate drop of the pH from 6.8 to 2.2 in the 'injection' compartment. This resulted in a rise of the surface potential due to polarization of the 'reference' electrode. Control experiments carried out in the absence of film showed that this rise in ΔV rapidly vanished with time. After about 5 min, the ΔV returned to its initial value. Changes in ΔV resulting from proton translocation along the various lipid monolayers were therefore determined from the surface potential measured before the addition of HCl, which can be considered as a 'reference' potential. $TH_{\Delta V}^+$ is the delay between H⁺ injection and the beginning of the change in ΔV . $\Delta \Delta V$ is the change in surface potential which is measured at equilibrium, when a plateau is again observed. The thin continuous curves are the recorder traces of the surface pressure π .

surface pressure (25 mMm^{-1}) were used. The TH_F^+ and ΔF values which were measured for the two lipids are shown in Table 1, together with those already reported for PE^{5,6}. As expected, the two techniques lead to similar TH^+ (around 2 min) for each lipid. From these values, PS would be a less efficient proton translocator than PE or PG, which exhibit the same behaviour.

translocator than PE or PG, which exhibit the same behaviour. The change in 'interfacial' pH which originates from proton conduction cannot be determined directly from the ΔF or $\Delta \Delta V$ values of Table 1. Nevertheless, and as a first approximation, this change in 'interfacial' pH can be related to the change in subphase pH for which the same ΔF and $\Delta \Delta V$ values would

Table 1 Changes in surface potential, surface fluorescence and pH for various phospholipids

 TH^+ , changes in surface potential $\Delta\Delta V$ and in surface fluorescence ΔF and measured equivalent bulk-phase pH and ΔpH values for films of phosphatidylethanolamine (PE), phosphatidylgycerol (PG) and phosphatidylserine (PS) (average of three to seven determinations)

^{*} ΔpH is defined as the difference between the initial subphase pH (6.8) and the measured equivalent bulk-phase pH.

[†] From ref. 5.

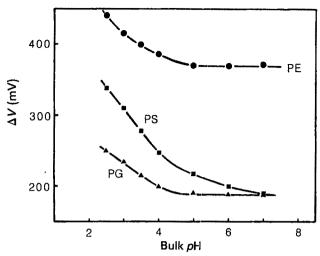

Fig. 3 Surface potential versus subphase pH titration curves. Phosphatidylethanolamine (PE), phosphatidylserine (PS) and phosphatidylglycerol (PG) were spread at a constant molecular area of 0.54nm², 0.66 nm² and 0.56 nm² respectively by stepwise deposition of the lipids onto various 1 mM phosphate subphases at the desired pH. For each lipid, these molecular areas correspond to a film surface pressure of 25 mN m⁻¹ at pH 6.8. Data presented are the average of five determinations.

be measured at equilibrium in surface fluorescence and surface potential against subphase pH titration curves, by reference to the initial subphase pH of 6.8. In the following, the change in 'interfacial' pH approximated in this way will be referred to as the 'equivalent bulk-phase' ΔpH .

Surface potential/subphase pH titration curves of PE, PS and PG are shown in Fig. 3. The apparent pK measured for our fluorescent pH indicator fluorescein thiocarbamide phosphatidylethanolamine (F-PE) in the presence of PG and PS (titration curves not shown) was not significantly different from that already determined for PE5.

The 'equivalent bulk-phase' pH and ΔpH values determined are shown in Table 1. For each lipid, these values indicate a monolayer in contact with an interfacial water phase more acidic than the bulk water phase. The equivalent bulk-phase ΔpH values found by fluorescence were always lower than those obtained through surface potential measurements, by about 2.5 pH units. Both approaches lead to the same decreasing order of proton conduction efficiency PE > PG > PS. This order agrees with the observed increase in TH⁺. Furthermore, control experiments showed that the aqueous phase which was sucked from underneath the lipid film (about 2-3 mm from the surface), just after protons were detected by fluorescence or ΔV measurements, was still at the initial pH of 6.8.

For each lipid, the observed differences in 'equivalent bulkphase' ΔpH can be accounted for by a steep pH gradient between a more acidic interface plane and the bulk of the water phase, as proposed in Fig. 4 for PE. Indeed, the surface potential senses the ionic conditions that prevail in the interface plane, where the polar headgroups are located. Fluorescein when attached to PE does not penetrate the lipid film but remains in solution in the water phase, hanging perpendicular to the interface plane⁵. The ionizable groups of this chromophore are difficult to locate accurately. From calculations based on molecular models, fluorescein should probe a thin layer of the interphase water, at a distance between 0.5 and 1.5 mm from the interface plane. A linear extrapolation of these ΔpH values over increasing distances into the bulk aqueous phase leads to the conclusion that the equivalent bulk-phase ΔpH would again be zero at a distance of about 1-3 nm from the interface plane.

Three main conclusions are to be drawn from this study. First, our fluorescence and ΔV data provide experimental evidence that proton conduction facilitated by phospholipids could occur

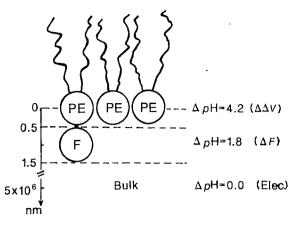

Fig. 4 Diagrammatic representation of the 'interfacial' pH gradient which is postulated to exist in the vicinity of a protonconducting lipid film. The indicated ΔpH values refer to the 'equivalent bulk-phase' ΔpH determined in Table 1 for phosphatidylethanolamine (PE) from the corresponding surface potential and surface fluorescence data. 4.2 is the ΔpH value sensed by ΔV measurements, in the interface plane. 1.8 is the ΔpH value monitored by the fluorescent pH indicator fluorescein thiocarbamide phosphatidylethanolamine (F-PE) which probes the interphase between 0.5 and 1.5 nm from the interface plane. A ΔpH of 0 shows that the pH measured by means of a pH electrode for a few millilitres of the subphase sucked up at a distance of about 5 mm from the water surface, just underneath the ΔV 'measurement' electrode and after an increase in ΔV due to proton conduction had been observed, kept the initial value of 6.8.

at the surface of energy-transducing membranes. This provides strong support for the semi-localized chemiosmotic hypothesis². Second, in our experimental conditions, large increases in surface potential were observed for each lipid tested. This means that in the case of a localized proton pathway, changes in the surface potential of energy-transducing membranes are expected. This could have consequences for certain membrane functions⁹. Third, the comparison between fluorescence and ΔV data strongly suggests that proton conduction is accompanied by a steep pH gradient from the membrane surface towards the bulk aqueous phase, the highest proton concentration being found in the interface plane. This means that protons are picked up and transported in this interface plane, where the polar headgroups of the lipids are located. In addition, the observed differences between each lipid in TH^+ and ΔpH values (Table 1) indicate that proton conduction depends on the nature of the lipid polar headgroups, as has been postulated^{5,6,10}.

It is finally worth emphasizing that the occurrence of such an interfacial pH gradient at the surface of an energy-transducing membrane might imply that the transmembrane bulk-to-bulk water phase ΔpH which is usually measured for the determination of the protonmotive force Δp , actually does not account for the real number of protons which are exchanged in the course of energy transduction.

We thank Professor Winterton for re-reading the manuscript.

As simple and friendly as soft gel chromatography. Powerful and productive as HPLC. Now uniquely combined into one totally new and radically different system. ULTRO-CHROM GTi. To separate, purify, quantitate and recover proteins, peptides, nucleic acids and even carbohydrates. With biological activity that can reach 100%. And in runs that only take minutes.

From pump heads to fraction collector, GTi means glass, titanium and inactive polymers. Giving you biocompatibility for complex protein mixtures. Replacing stainless steel at every liquid interface. Securing protection against buffers. Against corrosion by halide ions. Against denaturization by organic solvents. But with all the performance of a truly advanced and highly proven HPLC pump.

Meeting all your needs for multidimensional separation. Beginning with GFC. Switching columns for Ion Exchange, and then again for Hydrophobic Interaction Chromatography. Getting you higher resolution and increased purity all the way. With rapid analysis of sample complexity, continuously progressive purification and successful isolation of your important biomolecules. Completing separation strategies in hours instead of days. Solving particular problems with the most appropriate chromatography. Even reversed phase including microbore and fast LC. On just one system with unlimited potential. Giving you the most versatile chromatography in the world. Already being used by hundreds of biochemists. Getting them more results. Much faster. Much simpler. More reliably. One word says it all. GTi. You'll find it solving problems faster and better than any other separation system available. Get in touch with LKB. You're in for a winner.

CUSTOM SYNTHETIZED DNA AT EXTREMELY LOW PRICES

Prices (USD) per purified oligomer up to the length of 35:

				Basic fee	Per base
0.05	A260 un	its (~ 1	.5 μg)	8 5	5.50
0.2	A260 un	its (~ 6	μ g)	125	7.50
1	A 260 un	it (~30	μ g)	170	10.00

SPECIAL OFFER: FREE OLIGONUCLEOTIDES

FOR EVERY FIVE OLIGOMERS YOU BUY
YOU GET ONE ADDITIONAL OLIGOMER FOR FREE

WHY BUY MORE THAN YOU ACTUALLY NEED?

1 μg OF OLIGONUCLEOTIDE IS SUFFICIENT FOR:

- 10 oligonucleotide-directed mutagenisis experiments.
- 100 hybridization and gene synthesis experiments.
- 1000 dideoxy sequencing experiments.
- More than 1000 cloning experiments.

EVALUATE YOUR ACTUAL NEEDS BEFORE ORDERING!

GUIDE TO AUTHORS

Authors should be aware of the diversity of Nature - readership and should strive to be as widely understood as possible

Review articles should be accessable to the whole readership Most are commissioned, but unsufficited reviews are weigh (in which case prior consultation with the office is destrable).

Scientific articles are research reports whose conclusions are sill general interest or which represent substantial advances of understanding. The text should not exceed 3 000 words and say displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to Nature are ordinarily (188) words long with no market than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are

Matters arising are brief comments (up to 500) words (on articles and letters recently published in Nature. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washing ton. Manuscripts should be typed (double spacing) on one sale of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title shand exceed shipharacters in length. Reference fists, figure legends, etc. shand by on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one cope of the manuscript at their first appearance

References should appear sequentially indicated by super-scripts, in the text and should be abbreviated according to like World List of Scientific Periodicals, fourth edition (Bistlerworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Combisshed articles should not be formally referred to indess accepted of submitted for publication, but may be mentioned in the text

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for over illustrations are welcome Original artwork (and one copy of the manuscript) will be returned when manuscripts caused be published.

Important: Manuscripts of proofs sent by an courser should be declared as "manuscripts" and value 35 to present the imposition of Customs day and Value Added Fax in the United Kingdom

EXPLORING THE HU

THE EIGHTH INTERNATIONAL NATURE BOSTON, SEPTEN

Be in Boston in September with your colleagues and the publishers of NATURE, The International Weekly Journal of Science, for an update on some of the central issues in molecular biology for 1986 and beyond. Join us in *Exploring the Human Genome* as a distinguished panel of speakers share their research and outline their varying approaches to the concept of human gene therapy.

Human gene therapy is coming close to reality. An explosion of information on the human genome is flowing from the introduction of new methods. The mystery is being removed from such structures as the ends of chromosomes and the "junk" DNA that lies between genes. Ever more genes are mapped ever more precisely on to human chromosomes. Even where a gene cannot be directly mapped, its location can now be identified; great ingenuity is going into proceeding from a location to an exact site. In this way the defective genes of, for example, muscular dystrophy and cystic fibrosis will soon be identified. Knowledge of the mutations that underlie diseases, including cancer, is greatly increasing our understanding of the diseases and leading to new diagnostic techniques.

New products on view

In conjuction with the conference, there will be an exhibition of the latest scientific products and services offered by leading research labs, pharmaceutical firms, publishers and many others. Representatives will be on hand to discuss their products and to answer your questions.

Conference puts you in the heart of historic Boston

The conference setting is the The Boston Park Plaza and Towers, overlooking the picturesque Boston Common and Public Garden. You'll be just a short walk from Beacon Hill, the Theatre District, Government Center, and Copley Place. In minutes, you can be at colorful Quincy Market, the historic waterfront, and the Freedom Trail. This convenient location will offer you many opportunities for relaxation during your free time.

Day 1 — Gene Mapping

Economic revolution postponed for now

Governments have been succeeding in hiding from the consequences of industrial change. When will they begin to prepare for what lies ahead?

Opp things are happening to the world's economy, with the oddest consequences, one of which is that economists, the practitioners of the "dismal science", are now more dismal than usual. The familiar shrugging of the shoulders by which they disclaim the accuracy of their predictions is now often accompanied by protestations that they no longer understand the basis on which predictions should be made. Critics should be charitable. The conundrums which now abound betoken structural changes in the economic pattern of the world whose full effects are far from being realized.

The symptoms of impending change are striking. Here are a few. Earlier this year, it was widely expected that the dramatic decrease by about two-thirds of the international price of oil would have the effect of stimulating the economy of the industrialized West; now, after half a year, it seems more likely that economic activity will decline, which is one of the reasons why the New York Federal Reserve board, the US central bank, last week reduced the general level of interest rates to 5.5 per cent. During the same period, the value of the US dollar on the foreign exchanges has fallen, against some currencies by as much as a quarter, but there is no sign as yet that the US trade deficit, obdurately stuck above \$100,000 million a year, will be abated in the near future.

Meanwhile, the huge amount of debt run-up by the developing countries of the world with the commercial banks of the West remains substantially unchanged; after three years of fear that defaults might bring the whole house of cards crashing down, there has evolved a network of arrangements by which the debts persist (interest continues to be paid) but not even the banking community knows when, if ever, the principal will be repaid. Nevertheless, the stock markets of the world have just sustained a year-long bull market, bidding up the value of industrial stocks and shares to unprecedented levels. The proportions of people out of work in advanced societies are also unprecedented, as are the low prices of the commodities (not only oil) by which the developing countries of the world must hope to earn a living. What can be going on?

Paradox

The most sensible reading of these paradoxical events is that they mark the emergence of structural change in the pattern of economic activity on a scale that financial institutions can contemplate only in disbelief. The case of economic relations between the United States and Japan is a familiar pointer to what is happening. These years, the trade surplus of Japan amounts to roughly half of the deficit of the United States, but the effects of this imbalance are concealed by the willingness of Japanese to spend their surplus on investment in the United States, where steadily increasing proportions of industrial and commercial assets are owned by foreigners. The result is that the dollar has not depreciated against the yen by nearly as much as it would have done in normal circumstances. Japan does not seem as rich as it really is, while the true poverty of the United States is temporarily concealed. Both governments appear to benefit from these arrangements; Japan would no more welcome a more rapid increase of personal prosperity than the United States would enjoy a reduction of living standards. But this trend can be concealed only for a time.

Much the same is true of the strategems by which governments are seeking to conceal from themselves the patterns of impending economic change. Both in the United States and Western Europe (but also in Japan), governments spend substantial proportions of their domestic revenues on the support of agriculture, for example. In the United States, the cost will exceed \$30,000 million in the year ahead, something like a sixth of last year's budget deficit and rather more in 1987 if the US Congress manages to keep the total budget within the limits of the Gramm-Rudman Act.

The European Community's Common Agricultural Policy has the same effect. For the governments concerned, it seems preferable to sustain high-cost food production at levels the market cannot absorb (both by direct subsidy and by devices such as the artificial restraint of farm productivity such as the nonsensical European decision two weeks ago to ban the use of animal hormones — see page 762). The losers are not merely taxpayers but countries elsewhere in the world, chiefly developing countries, that might look for a more prosperous future in the development of trade in food.

Hiding

Once-prosperous governments are also bent on concealing from themselves the consequences of both the shift from manufacturing to service industries, under way for the past thirty years, and the shift, within manufacturing, from the products of heavy industry (such as steel) to those of light precision industry (such as electronics). Part of the motivation for this unwillingness to face reality is the sheer discomfort of rapid change, but there is also an underlying fear that countries such as Britain that used to be successful at heavy engineering are ill-equipped with the skills needed for survival in what has become the modern world. One glaring sign of the general fearfulness is the attempt now being made, by an alliance of European and North American electronics manufacturers and music publishers, to persuade Japanese electronics manufacturers to withold from the market the digital audio-recording equipment they are bursting to sell. If this scheme succeeds, where will protectionism end? Persistently high unemployment, made socially just acceptable by welfare schemes (as it should be), is a mark of the mismatch between the pattern of supply and demand.

This state of affairs cannot persist indefinitely. Water will sooner or later find its own level. But the readjustment, when it comes, could be catastrophic. What will happen, for example, in the slow-moving industrial communities when it turns out that the industrial equities whose prices have been bid up over the past several months by financial institutions buying financial assets with the intention of paying the huge impending cost of people's pensions turn out to be much less valuable than now? In this period of change suspended, the more far-sighted governments should be preparing themselves for what lies ahead, chiefly by investing in the intellectual skills that will be required. For most of them, unfortunately, propping up the past is the easier choice.

EPA discovers radon

The US Environmental Protection Agency risks stirring up a hornet's nest over radon.

It is a great shame that even the natural life is not entirely free from hazard, but that appears to be the case. For centuries, no doubt millenia, people and proto-people have been dying prematurely of natural causes - catastrophes, infections, climatic fluctuations and starvation, for example. Much of what passes for modern civilization is a marvellous defence against hazards such as these. Housing, by keeping people warm and dry, helps powerfully in this sense, which it is why it is one of life's little ironies that housing has also emerged, in the past few decades only, as a hazard in its own right. For houses, especially when they are of mineral construction such as stone, are also either a source of radon, the radioactive rare gas whose atoms are inescapably intermediates in the radioactive decay of the uranium and thorium series, or traps for it. One consequence is that all creatures on the surface of the Earth take in radon with every breath they breathe. Another is that those who live in houses may be exposed to extra amounts of radon generated from the construction materials. A third is that, in fashionable regard for energy conservation, houses are now less well ventilated and thus more efficient traps for radon.

The ubiquity of radon has been known for almost as long as radioactivity itself, the best part of a century. Only in comparatively recent decades, with better measurement techniques and accompanying conceptual refinements, has it become apparent that radon exposure must be, for most people, a greater source of biological hazard than other natural sources of radiation. The 1984 report of the UN Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) gives a good synoptic account of the problem. The hazards of this exposure, chiefly the risk of usually fatal lung cancer, have been estimated from records of the incidence of lung cancer in people occupationally exposed to radon in, for example, uranium mines (see, for example, Evans et al. Nature 290, 98; 1981). In very round numbers, the radon contributes more than a half of the average effective dose equivalent of about 2.0 mSv a year which people acquire on account of exposure to natural sources of radiation. The dose due to cosmic rays is roughly 0.30 mSv a year, varying with latitude and

Most public authorities appear to have awakened only late in the day to the importance of radon as a natural hazard, but the US Environmental Potection Agency (EPA) has been later than most. It seems now to be embarking on a crusade against radon pollution with a zeal and innocence that suggest it may have heard of radon only recently. In Washington two weeks ago, James A. Barnes, deputy administrator of EPA, acknowledged that "radon is a serious public health problem" and that "virtually no one" recognized it as such eighteen months ago. He added somewhat regretfully that radon, being a natural hazard, "does not lend itself to traditional regulatory solutions".

Precautions

What EPA has done so far is to publish two helpful booklets, one for members of the public explaining what the problem is and the other for householders and/or their builders suggesting what might be done about it (sealing off ground beneath houses, better ventilation and so on). There is also a modest programme of survey and demonstration, in conjunction with the states (especially Florida, Pennsylvania, New Jersey and New York), and the promise of more action in the future.

How to give radon the attention it deserves without creating panic? Part of the difficulty is that the two isotopes, ²²⁰Rn (commonly called thoron) and ²²²Rn, with half-lives of 55 seconds and 3.8 days respectively, are ubiquitous only in the sense that small concentrations are found in the atmosphere everywhere; on the basis of the total content of radon in the atmosphere (which,

measured in bequerels, is merely an order of magnitude less than that released from the Chernobyl reactor in April), the activity at ground-level should range from 1 to 100 Bq m⁻³, depending on the weather. But there are huge variations from one place to another, depending on such things as the upward flux of radon from the soil in the immediate locality, the flux from buildings and volcanic regions and even that artificially released into the atmosphere by drilling holes through granitic rocks in the pursuit of petroleum or of geothermal steam.

This is why the radon problem is a haunting problem. While the average effect of atmospheric radon on people living in the United States may be small, enough people are probably subjected to enough radiation dose for the personal consequences to be significant. Mr Barnes said that there may be 8 million people whose involuntary risk of death from lung (and other) cancer caused by radon and its decay products is comparable with that smoking from a pack of cigarettes each day, a lifetime chance of, say, less than one in six.

Costs

Mr Barnes' problem (and other people's) is that there is no way of telling what will be the financial consequences of avoidance. The retro-construction of buildings is not cheap, especially when the few people competent to do the work know that there is a panic on. So, in a roundabout way, the radon question raises a more general and difficult conundrum: by what means does a civilized community strike a balance between precaution and cost in the pursuit of an environment free from a natural risk? Can the community afford the cost of being as free from avoidable risk as it would like to be?

In due course, no doubt, in the special circumstances of the United States, the market may help solve Mr Barnes' problem. Realtors may be required to quote measurments of radon doses when they offer houses for sale, and may find that higher doses mean cheaper prices; that exceptional dwelling will be significantly if stochastically hazardous, people will for the first time find themselves picking and choosing where to live on grounds of radiation exposure.

Two particular considerations complicate EPA's problem: houses built in the 1950s in western states with US funds from materials salvaged from the tailings of uranium mines and subsequently found to leak radon were dealt with stringently at government expense, while the more recent recognition that radon concentrations in the so-called Reading triangle reaching north from Pennsylvania affect millions of people, on whose behalf such stringent standards will not be as readily applied.

Buildings accentuate the natural patchiness of radon distribution. The materials of which they are constructed are a source of radon, while the fact that they are of necessity enclosed allows them to become storage reservoirs for radon from the subsoil. The concentration of radon in the atmosphere of a room will be determined by competition between the rate at which the radon accumulates from external sources, abated by its natural decay, and ventilation in the sense of the rate at which air is exchanged with less contaminated air from outside.

The consequence is that radon radiation doses to the tissues of the human lung vary enormously with location and circumstances. The mean dose (arithmetical, geometrical or some other) will reflect regional characteristics, but the doses to which individuals are exposed will more often be very much greater than very much smaller (which is to say that the distribution is skewed). EPA's problem is that of helping individuals especially at risk to identify themselves, and perhaps to protect themselves, without alarming others. That, no doubt, is why the agency sounds so much like a newcomer to the scene. But it must also face the more enduring and, in the long run, more daunting task of knowing what to say to people whose radiation exposure is about average for where they live, but who know (perhaps by reading journals such as this) that their norm is higher than that of others.

Research donations

Tax bill provides fewer breaks for US education

Washington

CHEERS rang out late Saturday night 17 August in a room crowded with lobbyists, journalists and legislators, as a House of Representatives and Senate conference committee reached an agreement on a major overhaul of US tax law. The agreement came only after weeks of give and take among conferees, watched and prodded by a dizzying array of lobbyists, as they struggled to find a bill acceptable to both houses of Congress. The new law has the White House's blessing, and final passage is expected when legislators return from their summer recess.

The new tax law will mean significant changes for all sectors of the economy. The number of tax brackets for individual taxpayers will be reduced to two, with a maximum rate of 28 per cent, down from the current 50 per cent. For corporations, the top rate drops from 46 to 34 per cent. The bill is not intended to raise or lower total revenues generated by taxes. Instead, it is an attempt at a more equitable system, with narrower loopholes and fewer breaks for special interest groups. The tax burden will fall more heavily on businesses under the new law, although lowered rates for individuals will be offset by the loss of certain allowances.

Few segments of the economy emerged as clear-cut winners or losers, but one selfdeclared loser is higher education. Thomas Head, senior federal relations officer for the Association of American Universities (AAU), says education took a beating on nearly every item on its tax agenda. Head feels the biggest blow is the way gifts of appreciated property are treated. Under current law, the entire value of a donated gift can be deducted from taxable income. In the new law, the amount the gift has appreciated is used in calculating a special "alternative minimum" tax that is usually applied to wealthier taxpayers — those most likely to make sizeable donations. The cost of giving appreciated property is therefore much increased. Sheldon Steinbach, general counsel for the American Council on Education, says that 40 per cent of gifts over \$5,000 to universities and colleges come in the form of appreciated property.

Gifts from smaller donors are also likely to decrease because of a change in the reporting requirements for charitable contributions. Taxpayers are offered a choice between taking a standard deduction and itemizing their expenses: under the new law, only itemizers may claim a deduction for their charitable contributions. Only 20

per cent of tax payers are expected to itemize their deductions under the new law. Also limiting donations will be the lowered tax rates, as tax savings from contributions will be proportionately lower.

Gifts to charitable institutions, including those that support scientific research, will also decrease markedly under the new law. Dr Lawrence Lindsey of Harvard University has used an econo-

metric model to predict that total charitable donations in fiscal year 1988 would have been between \$72,000 million and \$75,000 million. But with the new rules total donations will fall by about 14 per cent, and donations by the wealthiest taxpayers by about 36 per cent, or \$1,000 million. The drop in charitable contributions that will be brought about by the inability of nonitemizers to deduct contributions is estimated at \$6,000 million, and that due to the overall drop in tax rates at \$4,000 million. Some charities are planning major fund-raising campaigns this year to take advantage of the existing law before it is superceded.

Major private research universities expect to be hurt by restrictions on access to the tax-free bond market. Tax-free bonds generally have lower interest rates than taxable ones, making them a cheaper way to borrow money. The new law places a \$150 million cap per institution on these bonds. Says David Morse, director of federal relations at the University of Pennsylvania, as many as twenty large universities will be shut out of the tax-free bond market. Smaller private colleges will be unaffected.

Universities are also dismayed by the change in tax status for scholarships and fellowships given to students. In the past, these funds have not been subject to income tax, but the new law makes any funds not applied directly to tuition or re-

quired equipment taxable. AAU's Head points out that since gifts are not taxable, students whose families can afford to give them money for their education would pay no taxes, but a poorer student on a scholarship could face a tax liability.

Another potentially expensive change for universities and colleges is the treatment of pension plans, says Head. These must be shown to apply equally to all university employees. Head says that most plans tend to be more favourable to faculty, and universities may have to cut back on faculty benefits to make plans equitable. In any case proving that plans are equitable will be a drain on university resources.

Not all the news for universities is bad. A new 20 per cent tax credit for industry support of basic research performed at universities and tax-exempt, independent research institutes appears in the new tax law. Dr. Melvin Eggers, Chancellor of the Syracuse University and vice-chairman of the Coalition for the Advancement of Industrial Technology (CAIT), an ad hoc group backing the new tax credit, says it will encourage closer cooperation between company and university researchers, speeding up commercialization of research efforts. According to CAFF's estimates, the new credit could bring as much as \$475 million in new research investments at universities. This is a relatively small amount compared to the estimated \$50,000 million industry spends annually on research and development, but supporters believe it is a step in the right direction. The credit will be available through 1988

Despite criticism that has been levelled against it in the past (see Nature 310, 615; 1984), the existing research and development tax credit is preserved in the new tax bill through 1988, although the rate drops from 25 to 20 per cent. Robert Lawrence. a senior fellow at the Brookings Institution, says that in real terms the credit only amounts to about 6 per cent because of the way it is calculated — the credit applies to spending above the previous three years average. Only 65 per cent of money spent in supporting university-based research figures in the credit calculations. While some have called for eliminating the research and development tax credit. Lawrence thinks the government must give industry even stronger incentives to encourage more spending on research

The new tax law's chances for passage when Congress returns are good, but some changes may still occur. The rationale for the tax reforms was to deemphasize taxation as a driving force behind business decisions. But taxes are bound to remain an important consideration for corporate decisions, and whole legions of tax lawyers will be kept busy figuring out just what the new realities are.

European agriculture

Politics before scientific advice

Last week's decision by the British agriculture minister to ban the use of growth-promoting hormones in cattle, following a European Commission directive to that effect, has drawn attention to an extraordinary incident last October. Then, the European Commissioner for Agriculture, Mr Frans Andriessen, suddenly suspended his scientific committee just four days before it was to prepare its final advice on the use of the hormones.

The committee, chaired by Professor G. E. Lamming of the Department of Physiology and Environmental Studies at the University of Nottingham, had reported in 1983 that the use of natural hormones such as oestradiol, progesterone, and testoterone in the form of implants in the ear of an animal was harmless to final consumers of the meat, even to pre-pubescent children, potentially the most sensitive group. Last year the committee, containing 22 senior European endocrinologists and toxicologists, was putting the final touches to its report on 'zenobiotics', or artificial hormones, such as zeronol and trenbolone when Commissioner Andriessen gave the order to stop. This effectively gagged the scientists as they are forbidden to reveal the results of their five-year study without the permission of the Commission; but it is widely believed that they would have given zenobiotics the same clean bill of health, provided use were controlled and monitored, as that gained by natural hormones. Just two months later, Andriessen successfully steered through the Council of Ministers a directive banning all agricultural use of hormones.

The British government, facing less public opposition to hormone use than its continental partners, voted against the ban in the Council of Ministers. But, faced with a possible loss of European markets if Britain failed to ban hormones, it now has little choice but to implement the directive. According to the Ministry of Agriculture. Fisheries and Food (MAFF). British meat exports to Europe are worth some £400 million annually. The use of hormones (to make the 50 per cent of British beef which comes from castrated cattle grow faster and produce leaner meat) probably adds only £40 million to meat values, MAFF estimates. Nevertheless Britain is pursuing its action in the European Court challenging the legality of the vote on the directive last December.

Lamming says he "does not want to get involved in politics", and is bound by contract to say nothing about his committee's report on the zenobiotics, but he is clearly disturbed at the possible consequences of the blanket ban on hormone growth promoters now in place in Europe. He believes that the ban could make the situation

more, rather than less, dangerous. Hormones in open use, are supplied from slow-release implants in the ear, a part of the animal not used for meat and where the implant can easily be detected. The implants diffuse small amount of hormones through the body of the animal; a pre-pubescent girl having 100 times more testosterone in her body than she could receive from a normal diet of hormone-treated meat; or a pre-pubescent boy 300 times the oestradiol he might receive from the same source. With the hormones banned, unscrupulous farmers will bury

the implants deep in the muscle tissue of the animals, probably in the most expensive cuts where inspectors are least likely to disturb a carcass, so certain slices of meat could contain far above average levels of hormone.

Lamming and his committee are, to say the least, put out by the Commission's decision. "We've done five years' work, collected voluminous data, and can't publish". Lamming for one will not be joining an ad hoc European committee again. But the major issue, which has risen again and again in Europe, is the preparedness of European ministers, who after all backed Andriessen's directive, to go ahead without listening to effective scientific advice.

Robert Walgate

Japanese space science

Joint project for solar maximum

Tokve

Japan's space programme may be tiny compared with that of the United States but its size is not preventing it offering a little hospitality to others. The Institute of Space and Astronautical Science (ISAS) has invited US researchers to place a soft X-ray telescope aboard their solar observation satellite scheduled for launch at the start of the next solar maximum in 1991.

The Japanese High Energy Solar Physics (HESP) mission follows ISAS's Hinotori satellite and the US Solar Maximum Mission that observed solar flares during the last solar maximum in 1981–82. The new ISAS solar satellite, Solar A, will be placed in low-Earth orbit where the US soft X-ray telescope and a Japanese hard X-ray telescope will be trained on the Sun.

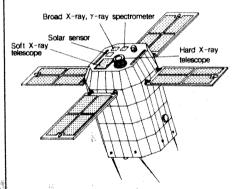

Designed to give high spatial and time resolution, both telescopes will allow second-by-second image analysis of solar flares as they grow and die. The hard X rays will reveal the hottest (greater than 30 million kelvin) kernel of flares during their flash phase, whereas the soft X rays will provide images of the cooler pre- and post-flash phases. If there is room for them, spectrometers will also be carried aboard the satellite.

According to the director of ISAS. Professor Minoru Oda. US participation in HESP will be funded through NASA's Explorer programme. An announcement of opportunity was made by NASA last March and official selection of the US team is expected this month.

Difficulties in setting up the joint project occurred, according to Oda, because of differences in approach between the United States and Japan. Whereas ISAS scientists gradually develop, refine and polish a project, and obtain final budget approval once a fairly concrete plan has emerged. NASA starts with a concrete plan and budget and solicits proposals. Other problems arose over the designation of the problems arose over the designation.

nation of principal investigators. But eventually, says Oda, a *tamamushi* agreement was reached (the *tamamushi* is an iridescent beetle whose colour changes according to the angle you look at it).

The satellite is expected to be about 2 m long and 1 m wide with three-axis stabilization to point the long axis towards the Sun. Weighing about 400 kg it will be launched to an altitude of 550–600 km by a

US and Japanese X-ray telescopes will share the new satellite.

Mu-3S-II rocket from the Kagoshima Space Centre during the August-September 1991 launch window. Apart from the US telescope, the total budget for the mission, which awaits final approval by Japan's Ministry of Finance, is expected to be about 4,000 million yen (£17 million), a mere fraction of the cost of launching a comparable satellite in the United States.

The cheapness of ISAS missions is easy to explain. ISAS scientists design, test, launch, monitor and sometimes even build their satellites and rockets, and although work is farmed out to private companies such as Nissan and NEC, there is no principal contractor. Final liability thus rests with ISAS, which substantially reduces the costs. Such an approach also has the advantage of great flexibility, but as Oda points out, it leaves precious little time for science.

David Swinbanks

Chernobyl report

Drama of human perversity

Vienna

The world's nuclear engineers gathered to hear the Soviet account of the Chernobyl accident on 26 April do not yet know whether they are at a wake for nuclear power or at a launching ceremony for a new generation of safe reactors. Nervously, they have crossed their fingers and praised the Soviets for their frankness.

The head of the Soviet delegation, Academician V.A. Lugasov, won over many critics with a gripping five-hour presentation of the authentic accident report, including personal asides hinting at disagreements on technical matters among Soviet officials. The highlight of the presentation was a video film, made under obviously hazardous conditions, showing the huge scale of the damage caused by the explosion of the No.4 reactor, with its contiguous neighbour miraculously undamaged. As in films of the Titanic at the bottom of the Atlantic, four of the eight reactor cooling pumps picked out through the gloom by a flickering spotlight seem as pristine as when they left the factory.

By Lugasov's account, the causes of the accident were not so much human error as human perversity. Plant operators in a hurry to complete a test of the reactor turbine's capacity to span a few seconds interruption of power supply, itself "poorly" designed, dealt with successive danger signals by disabling the safety systems meant to deal with them. In resignation, Lugasov said that when the RMBK-1000 reactor was designed 20 years ago, people had thought that human beings would be more reliable than automatic safety systems. Now he was not so sure.

The Soviet delegation has nevertheless acknowledged several technical defects of the reactor, whose merits are said to include simplicity and low cost. Lugasov pointed in particular to the disadvantage that, as excess steam forms in the water-cooled fuel channels, the reactivity of the reactor increases and also the complexity of the control system required to keep the power output stable.

Other RMBK reactors operating in the Soviet Union will be modified by 1987, chiefly by increasing the fuel enrichment from 2.0 to 2.4 per cent, with an estimated loss of 10 per cent of power output. Thereafter, there will be more radical modifications not yet decided.

The future of the Chernobyl site is much less clear. Two of the four reactors completed at Chernobyl have been decontaminated, but cannot yet be brought back into action for lack of housing for the operating staff now that the towns of Pripyat and Chernobyl are uninhabitable. Decisions remain to be made about reactor No.3 and the two other reactors whose

construction was under way at the time of the accident.

Lugasov's statement has also cleared up some of the questions that have been puzzling the West since the end of April. Thus, he said, there was no undue delay before the plant operators told Moscow of the accident, which meant that a team of specialists could be despatched to Kiev by 8 p.m. on 26 April. But the plant operators subsequently transmitted misleading information about the state of the reactor, the effect of which was to underplay the damage to the reactor and the release of radioactivity.

Lugasov also stoutly defended the decision not to evacuate 49,000 people from Pripyat until 11 a.m. on 27 April, more than 30 hours after the accident. "Strange as it may seem", he said, there was no significant contamination until 9 p.m. on 26 April, when it was judged safer to keep people indoors overnight.

The second wave of radioactivity after a week's delay was explained this week by the heating of the damaged reactor core to an estimated 2,000°C because of the thermal insulation of the clay and sand which, with other materials, had by then been dumped on top of it. More could not be added for fear of making the reactor foundation collapse, but there seems to have been no danger of a fuel meltdown.

John Maddox

Private money for AIDS research

Washington

THE US Public Health Service (PHS) wants to encourage private sector involvement in its efforts to find a vaccine to prevent acquired immune deficiency syndrome (AIDS). To that end, PHS spelled out in the 23 August Federal Register a more formal framework for collaborative efforts between the government and private institutions. The hope is that such collaborations will speed up the search for an AIDS vaccine, but some wonder whether the government has a sufficiently succulent "carrot" to encourage industry to play along.

Under the framework, PHS will not provide any financial assistance to its collaborators. Instead, it will offer knowhow from its component agencies - the Alcohol, Drug Abuse and Mental Health Administration, the Centers for Disease Control, the Food and Drug Administration (FDA) and the National Institutes of Health (NIH). This assistance could include patent licences, research results, facilities, animal models and animal testing, and help in formulating clinical protocols and clinical trials. PHS is interested in finding collaborators who will be involved in all steps in vaccine development, from basic molecular biology to clinical trials to marketing and commercial production. Companies unable or unwilling to participate in such a large scale project are encouraged to find others in the private sector to join with them in collaborating with the government.

PHS identifies two basic approaches to vaccine development that it wants to pursue. One is the development of a synthetic vaccine, generating viral antigens from whole virus, or using recombinant DNA techniques, chemical synthesis or anti-idiotype antibodies. The other is development of a live, genetically altered viral vector or attenuated vaccine. PHS will also consider other approaches, such as passive immunization, if they show promise.

A special committee established by the assistant secretary for health of the Department of Health and Human Services will make final decisions on collaboration following a review by the applicable PHS agency. PHS decisions will be based on an applicant's experience and ability to achieve its stated goals.

In the past, some companies have been reluctant to enter into collaborations with the government for fear that their proprietary research could be made public under the Freedom of Information Act. Lowell Harmison, science adviser for PHS, says companies will be protected from unwarranted disclosures as far as the law allows. but otherwise will have to give careful thought to how they word their applications. George Galasso, assistant director for extramural research at NIH, does not think these caveats will be sufficient. Companies that really have a promising vaccine approach "will go it alone", leaving the "also-rans" to seek government help.

Galasso also wonders whether formal collaborations with the government will speed the development of a vaccine. Scientist-to-scientist relationships have worked well so far, says Galasso, and will continue to be available when the need arises. Dino Dina, director of virology for Chiron Corporation, says having FDA help in developing acceptable standards for animal trials and initial clinical trials would be useful. But he feels a more efficient approach would be to make such information available to all comers.

Dina also worries that previous offers of "collaboration" from the government have turned out to be more take than give. But Harmison says the PHS plan is a fresh approach to cooperative arrangements. He hopes that the offer of government facilities and expertise will encourage companies with interesting ideas about vaccine development to pursue them.

Joseph Palca

Space station

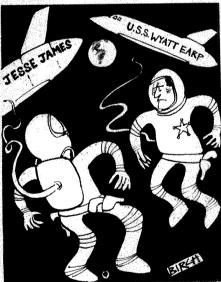

Taming the last lawless frontier

Washington

ALTHOUGH it will be several years before astronauts are working together in a multinational space station, it is not too soon for Congress to start considering legal questions that might arise, according to the Office of Technology Assessment (OTA).

Some US laws, Congress's research office notes in a recent background paper*, do not make much sense in space. The US Uniform Commercial Code, for example, with its definitions of personal property and real estate, and what is movable and what immovable, could not be applied "without serious uncertainty". The wisdom of applying the Buy-America Act is similarly unclear. And OTA notes it might be "inappropriate" to apply the Fair Labour Standards Act, with its stipulated 8-hour maximum working day.

More seriously, the application of intellectual property, product liability and export laws in a space station is likely to be important for commercial companies working on the space station. Although the 1967 Outer Space Treaty established some basic principles governing countries' responsibilities and liabilities in space, it leaves many questions unanswered. OTA recommends that Congress start thinking

immediately about how far US federal and state law can be applied in space, and how disputes might be resolved.

How to determine the jurisdiction of different countries over different parts of a multinational space station is seen by OTA as central. Both Europe and Japan are expected to contribute habitable modules; although the simplest thing from the US point of view would be to have everything under US law, this "may be politically unacceptable to other space station partners". OTA notes.

Patent law is likely to be especially diffi-

cult to sort out in space. There is already a variety of opinions on how far US patent law can be applied, and attempts in Congress to clarify the situation have not been very successful. Real disputes are likely to arise, since there are important differences in patent laws between nations.

In the case of criminal law, the question on enforceability also arises. So far crews have been highly disciplined and engaged in specific tasks. But as more people start to live and work in space there may be disputes. On space shuttle missions, the

commander has broad authority to enforce discipline. But if a British astronaut were to assault an American astronaut in the British portion of a space station, US laws could not be enforced without a prior agreement.

One way of avoiding complicated legal entanglements, according to OTA, would be for participating countries to enter in to "pre-launch agreements" modelled on the "status of force agreements" between members of the North Atlantic Treaty Organization which clarify legal questions about forces stationed in different countries.

*Space Stations and the Law: Selected Legal Issues. Office of Technology Assessment Background Paper, 1986.

UK universities

Government yields just a little

THE British government now seems willing to provide the extra money needed to prevent university closures — provided, that is, universities agree to reform and to their performance being monitored.

The news represents a victory for those who believe the only way to persuade the government to invest more heavily in the universities is by showing a quiet willingness to make improvements (or by being submissive, as cynics have it). Beginning in 1981, financial cuts have brought several universities to their knees: at least four are thought likely to have to close during 1987 if help is not forthcoming. The political embarrassment that this could generate in an election year, plus the new willingness of the universities to accept reform and monitoring seems, according to reports from the Department of Education and Science, to have persuaded the Secretary of State, Mr Kenneth Baker, to take out his chequebook, if not actually to sign the cheque.

Some of the changes the universities may have to accept are contained in the report on "Academic Standards in Universities" just released from the Committee of Vice Chancellors and Principals. Perhaps its most radical suggestion, for British academics at least, is that students should help appraise courses and lecturers. A host of other course evaluation measures are suggested: the number of applicants, the qualifications of entrants, degree results, percentage of drop-outs and so on. The report also seeks to lay down codes of conduct for external examiners, who will ensure that degrees awarded in similar subjects are comparable in standard in different universities; for postgraduate training and research; and for an appeals procedure for postgraduates who fail to be awarded degrees. The latter codes are intended to help deal with the embarrassingly high drop-out and failure rates among post-graduate students. The responsibilities of a doctoral supervisor

are made explicit for the first time and it is recommended that a statement to establish clear mutual expectations between student and supervisor always be drawn up.

The other issues on which the government wants to see progress are financial management, the creation of performance indicators so that whole universities might be appraised, and the rationalization of university departments that are judged too small or too weak. University performance indicators were set out in the Jarrat report last year; they include, among other things, the success of graduates in obtaining employment; publications by staff and citations; patents, inventions, and consultancies; prizes; and papers given at conferences (see *Nature* 314, 393; 1986).

The University Grants Committee has already set in motion an assessment of individual departments' research quality which seems set to lead to the closure of those judged inefficient. This has proved controversial; not only because of the uncertainties involved in assessment (see Nature 322, 219; 1986), but because small departments are emerging as the prime candidates for closure. While many will acknowledge this makes sense in areas where a critical mass of researchers is required to maintain expensive laboratory facilities, it may be a different story when it comes to subjects like the history and philosophy of science. There is a strong argument that the present situation, with sixty or so staff scattered over 25 universities, is the best way to allow many scientists to absorb some history and philosophy of science: to say that it should be concentrated in a few places is to denv its general relevance. Similar arguments over the rationalization of departments of philosophy are now provoking public debate and it is too soon to say whether philosophy will be seen as just a discipline for specialists. Alun Anderson US defence

Congress takes a moderate line

Washington

GROWING impatience with President Reagan's arms control policies has prompted the House of Representatives to take actions on its own. Before leaving for its summer recess, the Democrat-controlled House passed a decidedly "doveish" defence authorization bill and the Republican-controlled Senate also showed signs that it is ready for a more moderate buildup of US military capabilities.

Both houses of Congress have now completed work on versions of the defence authorization bill. Neither house went along with the administration request for \$320,300 million for the Pentagon: the House authorized \$286,000 million, while the Senate agreed to \$295,000 million.

The issue of chemical weapons has proven particulary divisive for Congress. The House agreed by just one vote to delay procurement of binary nerve-gas weapons until 1 October 1987. The Senate continued a string of close votes on chemical weapons and a measure that would have deleted funds for the Bigeye bomb, a new binary nerve-gas bomb that has failed many of its developmental tests, was defeated by one vote.

Although President Reagan has indicated that he no longer intends to abide by the terms of SALT II, the strategic arms treaty negotiated in 1979 but never ratified by Senate, opposition to that decision has been fairly strong in Congress. The House adopted a measure that would force the President to abide by SALT II by prohibiting funds to be spent on any weapons system that would be in violation of the treaty. The Senate would only go as far as requesting a Pentagon report on the consequences of violating the terms of SALT II and other strategic arms control

Spending on research on a space defence system was cut in half by the House, but authorized for the full \$278 million requested by the administration in the Senate. The Senate bill also includes \$28.5 million to begin procurement of a space defence system. Both houses made deep cuts in the administrations request for funding for the Strategic Defense Initiative.

The Pentagon officially runs out of money at the end of next month. Even if Congress cannot reach a compromise on the two authorization bills, similar language on weapons reduction schemes is included in appropriations bills working their way through Congress. One way or another, there is sure to be a shoot out on arms control before the Pentagon gets any more money. Joseph Palca Chernobyl accident

Fallout pattern puzzles Poles

"Hotspots" of radioactive fallout from Chernobyl are puzzling Polish scientists, Dr Zbigniew Jaworoski of the Central Radiological Protection Institute in Warsaw told a Japanese reporter. Mr Fumihiko Yoshida, of the Asahi Shimbun recently. The Japanese media have been particularly successful in elucidating details of the Chernobyl disaster and its aftermath - presumably the governments involved respect their unique positions as the only victims of a nuclear bombing. It was on Japanese television that Dr Valerii Legasov, deputy director of the Kurchatov Nuclear Energy Institute of the Soviet Academy of Sciences, revealed that almost all the safety circuits at the Chernobyl power station had been disabled during the unauthorized experiments that led to the disaster.

Dr Jaworowski, who is a leading adviser to the United Nations on nuclear fall-out, is recorded as saying that the hotspots. which measure several tens to several hundred metres across, exhibit levels of radio-activity some ten times higher than the surrounding area. The spots are roughly circular in shape and, in the immediate post-Chernobyl period, it appears their outline could be mapped by field observers with geiger counters. Analysis shows that ruthenium (an element whose name, ironically, derives from the Latin designation for Ukraine) is the major radioactive material in the hotspots, although there are a few in which lanthanum or barium isotopes predominate. Although most common in north-east Poland, they could be observed all over the country. Dr Jaworoski reportedly

Details of the level of radioactivity of the hot-spots have not been given, but similar ruthenium particles deposited in Sweden have registered levels of 1,000 -10,000 becquerels per particle.

The Polish scientists, Yoshida reported. have no idea why the hot-spots are so widely distributed, nor why they consist predominantly of ruthenium. An apparently similar phenomenon in the Mahileu rayon of the Byelorrusian SSR (well away from the total exclusion zone) has been attributed to a freak rain-shower, but, as the "self-help" advice issued by underground Solidarity makes clear, the one thing the Poles were longing for in the immediate aftermath of the disaster was rain which would, they hoped, wash away the air-borne hazard. Dr F.B. Smith, an expert on air-borne pollution from the UK Meteorological Office at Bracknell, suggests that the radioactive material was deposited by dew, which is sensitive to the temperature differences generated by soil-type and land use. Vera Rich

Japanese mega-prizes announced

ONE of science's newest - and biggest prizes has gone to Professor G. Evelyn Hutchinson of Yale University and Professor Nicole M. LeDouarin of the Institut d'Embryologie, Nogent-sur-Marne.

Each will receive the Kyoto Prize medal and Y45 million (\$300,000) at a ceremony to be held in Japan in November.

The prize was set up last year by Kazuo Inamori, founder of Kyocera Corporation, Japan's most famous and fastest-growing hightechnology ceramics company. In just twenty-five years Kyocera has "by the grace of God" grown to produce annual pre-tax profits of Y53 thousand million. That has made it possible to endow the Inamori Foundation with Y20,000 million to provide for the award of an annual prize.

The aim of the prize is to en- Prizewinners LeDouarin and Hutchinson - each with courage balance between scien- \$300,000 to spend tific and technological development on the one hand and psychological and emotional maturity on the other: equilibrium between the "ying and the yang, the light and the dark" is sought.

Many would say that equilibrium has

been achieved by Professor Hutchinson who is known both as an essavist and a scientist. He did much to establish ecology as a science and was the first to develop the concept of the ecological niche. Born in England in 1903, Professor Hutchinson is now an emeritus professor and still writing and researching.

Professor LeDouarin, born in 1930, is known for the work that led to the creation of quail-chicken chimaeras. The distinctive properties of the tissues of the two animals make it possible to follow previously-unobservable events in development.

Belief in miracles

Sig-With regard to R.J. Berry's question "What to believe about miracles" (Nature 322, 321, 1986), I think it more interesting, and more of a scientific question, to ask how one can understand and explain belief in miracles. Belief in miracles is a widespread and very influential psychological phenomenon, underpinning value systems and cosmologies that have shaped the history of the world. The events called "miracles" may or may not have occurred in the form in which they are described. but their existence as a phenomenon of social fact is very real. This deserves serious investigation.

The main problem with most miracles is the ambiguity of testimony. Often they were reported long after the event, at second-hand; even if the reports are firsthand and attested to "by thousands", it is usually one person who wrote the description. So the data are usually shaky.

There are therefore, a variety of possible hypotheses. One is that the event occurred, and that it was due to divine intervention in some form. A second is that the event did not happen at all, that nothing remotely like the event occurred, but that people at a subsequent date constructed mythical events and actions surrounding charismatic figures. This is a virtually universal psychological phenomenon, and indeed there are certain common myths that existed long before their adoption by Christians - the virgin birth, and the death and resurrection of the God, for example, and many religions whose origins are in floodplains have Noah-like heroes in their mythology.

A third hypothesis is that something happened, but there was inadequate information about it, and the ambiguities are resolved in a way that provides both consistency and charisma - such psychological processes are demonstrated for every first-year student in social psychology in laboratory classes.

These explanations do not deny the possibility of miracles, but they do bring into question Berry's distinction between domains of faith and domains of science by asking what parameters of miracles are scientifically interesting. Indeed, Berry's point about reductionism is an important one, and something that the newer sciences and social sciences have been plagued with. Setting limits to one's science is a way of achieving rigour, by defining what is possible for investigation given the methodological resources available. But such rigour becomes rigor mortis if the limits set are those of one's actual and present methodological constraints, not those of some potential and future, more sophisticated methodology. Developments in psychology have frequently depended on researchers going "off limits"

and defining a problem as interesting some time before the methods existed to study it; undoubtedly this is true of all sciences. Berry argues that it is reductionist to say, in effect, that because we cannot study them (given present techniques). miracles are impossible; he is, I would argue, equally reductionist in saying that it is not possible to investigate miracles using scientific measures. It depends which science one applies to the problem. HELEN WEINREICH HASTE

What's in a name?

Sir-That (novel carbon cluster C,) which we call Buckminsterfullerene has excited considerable interest while the name we have chosen has stimulated comment². Although many have approved of this name, there have also been criticisms that it is too long (one should consider the IUPAC name), that it is clumsy (which is irrelevant), that nobody has heard of Buckminster Fuller (the name thus has educational value) or that an injustice has been done to almost everyone who has played with symmetrical objects from Plato and Archimedes to Stanley Matthews (the professional footballer).

The molecule we believe we have discovered consists of a sheet network of carbon atoms linked to form a highly resilient hollow sphere. The names of Plato and Archimedes are linked with the regular and semi-regular solids, an association, by the way, which may not be totally justified. The earliest hollow association I have found is in the work of Leonardo da Vinci3.

Buckminster Fuller showed that a hollow, light, strong structure could be constructed out of a network of struts using the known principle of Euler that, for closure, 12 pentagonal configurations must be dispersed among the hexagonal ones. The spherical structures such as the Montreal Expo '67 dome, the Epcot Dome and numerous radomes are constructed to take advantage of the lightness, strength (the strains are evenly distributed) and of course the internal cavity. that such a geodesic dome affords. C, is a geodesic carbon atom network with a very strong inert structure and a large central cavity that can trap other atoms. These three major properties are important for this molecule's behaviour and have direct analogues in the success of Buckminster Fuller's geodesic structures, factors that are not inherent in other names. C₁₀₀ Buckminsterfullerene itself is only one

member of a set of structures (C₁₄-C₈₀) that appear to be closed and, although they must have 12 pentagonal configurations, do not have to have t-icosahedral symmetry. Buckminster Fuller also considered such structures.

Spanish universities

SIR-In two recent issues of Nature (319, 710 and 322, 198; 1986) Juan A. Subirana and Pedro Puigdomenech have pointed out the danger of "inbreeding" in the Spanish universities, as a consequence of the new recruiting system for academic posts. That this danger is becoming fact is demonstrated by the first examinations carried out under the new system.

In most cases, the process of appointment seems to have been a mere formality, the final decision being taken before the examination. Nearly all those obtaining posts were the so-called "official candidates", who were proposed and supported by the university departments before the vacancy was publicly announced. Such candidates began with at least two out of the five votes of the selection committee, those of the members of the department concerned. Other applicants, even those with scientific qualifications superior to those of the official candidates, were often eliminated on the basis of subjective arguments. Work carried out at foreign institutions was undervalued, while some foreign candidates were eliminated by questions such as "What are the idiosyncracies of local students?".

In those circumstances, it is unlikely that many Spanish graduate students and postdoctoral fellows now working in foreign scientific institutions will ever get positions at Spanish institutions. This will not encourage the return of such people to Spain. As a logical consequence, the standard of scientific research in Spain (already much lower than in other Western European countries) will not be raised in the future. This is a serious deficiency in a law that otherwise has many positive features and that was intended to improve the general level of Spanish research. It is a matter of great urgency to reform this system by a new or additional policy.

Law and genetic testing

SIR-Bains observes that genetic screening may have attendant legal ramifications. This has certainly been demonstrated in the United States.

The expanding ability of medical science to predict and detect defects before birth may have important applications in clinical medicine. Genetic counselling and prenatal testing may potentially provide valuable information to patients planning families about the likelihood of various defects in their offspring. The development of various genetic screening techniques, at least in the United States, has further spawned the birth of various classes of lawsuits. "Wrongful pregnancy" actions refer to cases where the parents of a child file a claim for the monetary and emotional damages suffered as the result of giving birth to a healthy, albeit unwanted, child2. The action may arise where a child's conception was due to the alleged negligent performing of a sterilization procedure. "Wrongful birth" suits are those instituted by parents claiming that they would have avoided conception or terminated the pregnancy had they been advised of the risks of birth defects in their offspring'. "Wrongful life" cases are instituted by the infant and allege that, as the result of the negligence of the defendent health-care provider, birth has occurred. The infant is claiming essentially that the defendant has wrongfully deprived the parents of information, which would have resulted in the child not being born.

The three classes of lawsuits are thus different. Wrongful pregnancy cases typically involve a healthy, although unwanted, child, whereas wrongful birth actions normally involve planned children who are born deformed. Both actions are normally brought by parents. However, the wrongful life action is brought by the infant. Allegations in recent, selected lawsuits have involved the failure to diagnose Down's syndrome during pregnancy', failure to diagnose rubella suffered by the mother during pregnancy resulting in the birth of a rubella baby with severe congenital defects³, failure correctly to type and record maternal blood and the later birth of a child with erythroblastosis fatalis', the "wrongful birth" of children suffering from fetal hydantoin syndrome associated with the mother's use of dilantin during pregnancy', negligent performing of a vasectomy and the negligent performing of tubal ligation'.

With the increased knowledge in the field of genetic screening, there has been a concomitant recognition by various courts that the appropriate standard of professional care may require the use of available, pertinent prenatal tests and genetic counselling, particularly for patients at high risk of having children with birth defects. Perhaps it may be helpful to seek definitive legislative guidance concerning the vexing legal questions potentially raised by genetic screening.

Models of man

SIR-In the context of the diversion of psychological research funds to cognitive science and computing projects, the argument below must be considered:

There are two flaws in computational models of man: (1) in human beings there can be no certainty what the programs are; (2) in human beings the database is unknown and different for every person. It therefore follows that computational models, being quite unlike the human case, are doomed to failure.

Help for Africa

SIR-Michael Spencer's letter (Nature 322, 10; 1986) prompted me to read again your leading article "Who will pity Africa?" (Nature 321, 548; 1986). Pity and political posturing seldom assist the objective assessment of any problem, least of all the vast and complicated set of problems that afflict Africa today. Spencer highlights some of the external political and economic pressures, whereas your leading article, like the United Nations' statement of early June, drew attention to the contributions to the chaos made by some of the African governments themselves. All these have to be taken into account, and much else besides, not least the vastness and heterogeneity of Africa itself - some 45 separate states and ecological conditions ranging from complete desert to tropical rain-forest, with montane and temperate regions besides.

You call for "a political clearing-house for good ideas that have already contributed to the improvement of Africa's conditions on a small scale... which... could be spread more widely". I hope your call will be heeded, but I would suggest that the emphasis should be not so much on good ideas as on good projects that have proved themselves over a reasonable period of time.

As Spencer says, there has been no

shortage of good ideas, but some of these have proved to be disastrous. They range from simple wells in arid regions which have attracted so many people and their animals that the surrounding land has been destroyed, to multi-million dollar irrigation and farming projects that have impoverished the local farmers and their land

Most of Africa never was and never will be "a Garden of Eden" - the ecology is not like that - but there are instances, past and present, where sensible efforts, with or without outside help, have led to real improvements in the lives of ordinary people. We need to hear more about these, and less about who is to blame for the present troubles.

Darwin's yellow rain

SIR-In the light of the continuing controversy over yellow rain, it might interest your readers to know that Charles Darwin observed and reported a case of yellow rain. The report was quoted in the 18 July 1863 issue of the Gardeners' Chronicle and Agricultural Gazette¹. The letter from Darwin reads in part:

A very slight shower, lasting hardly more than a minute, fell here this morning (July 2) about 10 o'clock. My wife gathering some flowers immediately afterwards noticed that the drops of water appeared yellowish. and that the white roses were all spotted and stained. I did not hear of this circumstance till the evening; I then looked at several roses and Syringas and found them much stained in spots. Between the petals of the double white roses there were still drops of the dirty water: and this when put under the microscope showed numerous brown spherical bodies, 1/1000 of an inch in diameter, and covered with short, conical transparent spines.

Darwin goes on to describe additional small particles "only just visible with a quarter-inch object glass". The author of the article, designated only as M.J.B., reports examining rose petals forwarded by Darwin, and observing "multitudes of irregular bodies so minute as to present the Brownian molecular motion". M.J.B. concludes that "it is quite astonishing what a multitude of bodies are carried about by the wind in the form of dust"

Indeed, it is equally astonishing that we should still be arguing about yellow rain 125 years later.

Science and faith

Sir.—In seeking to refute the beliefs and arguments of creationists, J. Richard Wakefield (*Nature* 320, 392; 1986) makes four unjustified generalizations to which I must object as a Christian and as a scientist

My first point deals with the limits to science. Wakefield states categorically that nothing is potentially beyond science. This is questionable. The scientific method is empirical and depends on testing one's hypotheses against what happens in the real world. Its conclusions ("scientific laws") are inductive and provisional, and they remain open to revision in the light of new and more comprehensive experience. Scientific knowledge is still partial and incomplete, and many things lie beyond its boundaries. The day may come when science can satisfactorily describe, predict and explain every phenomenon in the cosmos that can be subjected to scientific analysis; but the possibility that the universal set of real phenomena extends far beyond the finite subset of scientifically verifiable phenomena will remain and cannot be disproved by science. How can science ever illuminate what lies behind the beauty of form, of poetry, of music, of humour, and of human emotion? Humans are physical, rational, intuitive, emotional, personal, cultural, social, moral and spiritual beings. Science is only one of the forms of knowledge available to us; we are familiar with different kinds of knowledge in art, in love, in politics and in religion. Science is not served by making exaggerated claims on its behalf, any more than is creation-

My second objection is to Wakefield's view of faith, which he defines as "belief without evidence". St Paul, however, taught that "faith gives substance to our hopes", faith is "the proving (or test) of things not seen" (Hebrews 11.1; New English Bible, Revised Standard Version emphases mine). In the classical tradition of Christian experience and understanding, faith is trust that leads to action; and the outcome of living by faith, in the testimony of countless Christians, amply substantiates and justifies it. As science generally considers it good practice to test hypotheses before discarding them as invalid, I suggest that Wakefield and those who sympathize with his views subject mainstream scriptural Christian faith to the same test before they totally discount

Third, according to Wakefield, "we all know that science accepts nothing on faith". Science can provide us with statements about degrees of probability and correlation. To speak of the provisional and ever-cautious statements of science as if they were eternal proclamations of certainty and causality is to distort the truth.

As D.H. Koobs points out (*Nature* 319, 172; 1986), to assert today that the Universe and its life forms occurred spontaneously remains "clearly a matter of faith".

Finally, Wakefield claims that "creationists do their best to twist, lie, fabricate, misrepresent all they can of reality to deceive their followers and the lay public". While this may be true of some creationists. I cannot believe it is true of all. It is possible to hold a creationist view of the origin of life and the Universe with sincerity and intellectual integrity. And in the interests of scientific objectivity, it must be pointed out that scientists, too. have sometimes distorted the truth: let us remember Burt's obsessional prejudices about race and IQ which he dishonestly presented as if they were real experimental findings.

VALERIE VENTURA

Risk analysis

S_{IR}—S.O. Funtowicz and J.R. Ravetz (*Nature* 321, 644; 1986) are, of course, correct in writing that society must recognize that large improbable accidents can and will happen, whether they be collisions of Boeing 747 aircraft over Wembley Stadium during a Cup Final, or the failure of a nuclear power plant.

Their rejection of probabilistic risk analysis (PRA), however, is factually incorrect. It was not used in either of the two examples he cites — Three Mile Island or Chernobyl. In 1977, the US Nuclear Regulatory Commission instructed its staff not to use PRAs in the licensing procedures. As a result, nobody calculated for a Babcock-Wilcox reactor until the afternoon of 28 March 1979. If they had. the weakness of the operating procedure would have been quickly recognized and the accident at Three Mile Island avoided. In spite of numerous reports and discussions, both official and unofficial, nobody in the West has seen a PRA for Chernobyl. I do not believe that a complete one exists.

It is the procedure of thinking carefully about accidents, using logically plausible scenarios, that is our best and possibly our only defence against these scenarios occurring. This is what a PRA accomplishes.

Some responsible, competent person must have thought through the problem enough to derive a number with its uncertainty. Whether Funtowicz and Ravetz believe the number is comparatively irrelevant. But they should not discourage the procedure itself, which is almost the only procedure that we have.

Pesticide regulation

SIR—I appreciated Kenneth Mellanby's letter in *Nature* (321, 465; 1986) about my objection (*Nature* 320, 391; 1986) to a sentence in Lord Ashby's review of John Sheail's book (*Nature* 318, 21; 1985).

I have admired the British method of pesticide regulation, and Sheail performed a good service by describing the collaboration there between industry and government.

I certainly did not intend to imply that it was Mellanby's British colleagues who resorted to "such unscientific methods as deliberately distorting or omitting all the data that refuted their (anti-DDT) allegations". Instead I had in mind only the work of several notorious US scientists, especially some employees of our federal Fish and Wildlife Service and a few in the California Department of Fish and Game. Their statements were frequently published, without competent peer review, in magazines such as Science. BioScience. Scientific American and various "bird" journals. Specific refutations of their allegations have been published elsewhere by many concerned US scientists. but were ignored by the US Environmental Protection Agency (EPA).

EPA joined the attack, and sought to direct a worldwide condemnation of agrichemicals and chemicals used to alleviate insect-borne disease outbreaks, via its Toxic Substances Control Act (TSCA). In response, British Science Attaché Alan Smith was applauded by over 600 specialists at a meeting called by EPA to discuss the act when he stated: "This draft is like the jabberwocky of Lewis Carroll the language of chemistry mixes uneasily with the language of metaphysics and the overlay of legal jargon makes the whole incomprehensible." After calling it an "absurd piece of gobbledegook", Smith suggested that EPA should "not presume to legislate for the Universe and the whole human race" and that "there is a limit to the number of times even the greatest country in the world can afford to appear ridiculous in international affairs" (Science 196, 1182-83; 1977).

Although DDT is no longer used in the United States, false claims about it continue to be repeated. The reasons are varied, but are well-known. The same sort of campaign that succeeded in banning DDT has more recently been directed against 2,4,5-T, malathion. DES and many other useful chemicals of very slight hazard to man or the environment. Unless the scientific community actively exposes such false statements as have been made in journals and indicates disapproval of those who deliberately make them, the human race faces a very bleak future.

J. GORDON EDWARDS

San Jose State University, San, Jose, California 95192, USA

New ways with interatomic forces

Attempts to calculate the properties of real materials from those of their constituents have never been outstandingly successful. New, but still empirical, techniques may help.

Since the year dot, or thereabouts, all kinds of people have been calculating the properties of matter of various kinds by making assumptions they know to be inadequate about the forces between constituent particles. The process continues, and discontent with the assumptions is, if anything, made more explicit by the availability of computers and the associated computer codes that will allow the treatment of systems large enough to be considered "realistic". But supply tends to grow to meet demand, and the invention of novel schemes for representing interatomic forces is now also flourishing. One such is a way of representing long-range interatomic forces developed by a group based at the University of Trieste (F. Ercolessi, E. Tosatti and M. Parrinello) and applied to the structure of the surface of gold crystals (Phys. Rev. Lett. 57, 719;

The problem of calculating ab initio the properties of a material is indeed intractable. Even that model of the ideal gas in which the atoms are perfectly elastic solid spheres is useful only for as long as the spheres are not so large, relative to their container (again assumed perfectly elastic) that geometrical effects make them clump together in some sense. More realistically, the forces between pairs of atoms in, say, a monatomic gas are better represented by a distance-dependent mutual potential energy leading to forces that are repulsive at short distances (reflecting the solidity of atoms) which may be offset by attractive forces at greater distances. Van der Waals is the name to conjure with; physically, what happens is that random intra-atomic fluctuations giving individual atoms an electrical dipole moment will tend to synchronize with the instantaneous dipole moments of interacting atoms, dragging the two together, which is why gases whose constituents are either polar or highly polarizable molecules depart most conspicuously from the perfect gas laws.

Mischievously, real substances are more cussed than these simple examples allow. Even in gases, three and multibody forces are bound to be relevant, and properties may depend not only on the positions of atoms or molecules instantaneously, but on their velocities as well. A further complication, especially when the average inter-particle distance is small, is that there may be literally no limit to the distance over which inter-particle forces

exert themselves because of cooperative effects in which the miscroscopic interactions have the effects of enforcing long-range order, when a material behaves as if the range of the physical force between a particle and the environment of which it is a part is literally infinite.

So what happens in, for example, a metal, which may be taken, for the sake of argument, to be a lattice of positively charged ions embedded in a sea of negative electricity? Simple calculations based on the assumption that the ions interact with each other by some defined interionic potential energy will not wash, because the electron sea is of necessity a long-range system whose collective properties and, in partucular, energy may not be simply expressed by the distance between the members of an arbitrarily chosen pair of atoms.

Ideally, people wishing to calculate the binding energy of a metal should proceed differently: first, make an assumption about the geometry of the ion lattice, then calculate the allowable quantum states of electrons, finally allow that the electron distribution will seek a lower level of energy in which ionic charges are more completely shielded from each other (which is where the Thomas-Fermi and other selfconsistent field calculations come into their own). The results are reasonable enough, although not especially persuasive, for one thing because nobody is confident of being able to adapt the selfconsistent calculations to the real case in which the ions of the ion-lattice are in motion, as they must be.

That is why there is such ample room for more empirical ways of tackling the problem by the invention of novel ways of describing the forces between ions in, say, a metallic crystal. The obvious difficulty is that the bulk properties of metals do not provide a sufficiently stringent test of possible refinements of assumed interatomic force laws, all of which must have certain general properties in common. But distortions at the surfaces of metallic crystals to the regular distribution of ions in the bulk may be an opportunity for verification, which is where Ercolessi and his colleagues begin, with the surface structure of metallic gold.

Like many other solid lattices, but more markedly, the surface of a metallic gold crystal is not a simple projection onto a crystallographic surface of the structure of the crystal lattice in bulk. Instead, the atoms of this structure, whose unit cell is face-centred cubic, appear on simple crystallographic surfaces — such as (001) — to be arranged in stripes, five rows of atoms wide within which atoms are arranged on a triangular rather than a square pattern. This has been shown experimentally by, for example, low-angle electron diffraction.

Ercolessi et al. apply to this structure a force-law they have developed in other connections, one that allows not only for pair-wise forces between atoms (including other than pairs of nearest neighbours) but for a generalized glue-like force which has the effect of making it energetically adventageous, in a system such as a metallic crystal, that the coordination number should be increased. Their two-body force is conventional enough, implying repulsion at short distances, a minimum energy at about 0.27 nm and attractive forces at greater distances. The glue force is harder to visualize, but represents a kind of tradeoff between high coordination number and proximity between pairs of atoms.

The outcome is remarkably suggestive even though it leaves much to be desired. By a suitable choice of the empirical constants in the force laws, five-row stripes of atoms can indeed be made to appear on the simple surfaces of gold crystals. The obvious snag is that there seems very little hope of being able to calculate either the pair-wise forces or those that represent the glue from what might be called first principles. Even so, especially because of the importance of, for example, the surface structure of semiconducting materials such as silicon, there is every prospect that this new technique of calculation will quickly become fashionable. It may even become a fashion that will last.

The situation in the calculation of the properties of metals, in other words, may soon not be very different from that in the calculation of the properties of gases half a century ago. Then it was that people were aware of the complexity of the pair-wise interatomic force as well as of the need to pay some attention to three and multibody forces. The force-laws were for the most part empirical, but it is remarkable how useful they proved to be. Nobody will weep if there is a period, perhaps a long one, during which the calculation of the properties of metals is as much a matter of finding, through trial and error, which methods work and which do not.

John Maddox

Neurochemistry

Lessons from large molecules

from William S. Agnew

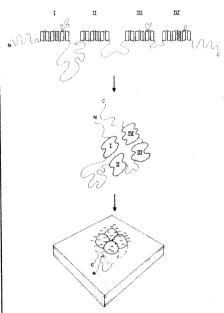

THE nervous impulse is one example of a major, easily observable physiological phenomenon that results from the action of a particular type of protein molecule, in this case the voltage-sensitive sodium channel. The nature of the smallest molecular unit that constitutes a functional sodium channel is, therefore, of considerable interest. In the most recent work from the laboratory of S. Numa, reported by M. Noda and co-workers on page 826 of this issue (ref. 1, see also refs 2,3), the authors use molecular cloning techniques to provide convincing evidence that the minimum molecular element constituting a sodium channel is a large, heavily glycosylated polypeptide of relative molecular mass 260,000-295,000 (260-295K). This finding helps to constrain models for ionic permeation and voltage-dependent gating mechanisms, and has probably resolved the question of the obligatory role of the small peptides found in preparations of brain and muscle channels.

The origin of this question lies in studies in which sodium channels have been isolated, mainly from three tissue sources: eel electroplax4.5, mammalian muscle6 and brain7. Common to all three preparations are the 260-295K glycopeptides. Brain channels include two smaller glycopeptides, 36 and 33K, the former linked to the larger peptides by disulphide bridges. There is at least one peptide of 39K in muscle, although no small peptides have been found in the electroplax protein.

Each of these preparations, including the single-peptide electroplax protein, has been successfully reconstituted in biochemical and biophysical studies8-10 Because of the similarities of the large peptides, these findings appear to argue against a mechanistic role for the smaller subunits. Nevertheless, evidence from subunit-dissociation studies led Catterall and co-workers to conclude that they are involved in neurotoxin binding", suggesting that they are essential in channel activity in vivo, perhaps for activity or for expression at the cell surface.

The three recent reports from Numa's laboratory1-3 cast the whole constellation of questions about sodium-channel structure and function in a new light. In the first of these2 the authors cloned and sequenced the 8-kilobase complementary DNA that encodes the large peptide of electroplax. The deduced amino-acid sequence is consistent with previous compositional studies and provides an intuitively satisfying indication that the 208K polypeptide portion of the glycopeptide probably folds into a tetrameric structure.

But messenger RNA transcribed from this DNA apparently does not yield functional channels when microinjected into frog oocytes, possibly because of failure of post-translational modifications. Thus, in a second study'. Numa's group cloned the large subunit of the brain channel, only to discover that in this tissue not one, but at least three species of channel are expressed, closely related both to one another

Sodium channel amino-acid sequences suggest that a tetrameric bracelet of domains (I-IV) contain most glycosylation sites and predicted membrane-spanning a-helices. Negative surface charges derive from sialic acids and a possible cytoplasmic domain could act as a substrate for protein kinases or mediate interactions with other proteins.

and to the electroplax protein. These findings at least briefly raised the spectre that there could be as many as six smaller peptide constituents: identifying which are associated with and required for the activity of each large peptide might have demanded an entire new round of detective work before mutagenesis studies could begin.

In the study reported in this issue, the authors prepared messenger RNA by in vitro transcription of each of the three variant brain clones. When the RNA from one of these, rtII, is microinjected into frog oocytes, comparatively large voltageregulated sodium currents appear after 3-5 days of incubation. These currents are tetrodotoxin-sensitive, sodium selective and exhibit voltage activation and inactivation. Activation- and inactivationgating parameters are within the range expected for conventional sodium channels. Expression is not enhanced by ad-

dition of low molecular mass poly(A)' messenger RNA from brain, consistent with earlier fractionation studies. The possibility that the protein has combined with endogenous small peptides still needs to be tested directly, but seems unlikely because oocyte sodium channels are markedly different from those produced by RNA injection.

Thus, at least one of the brain-derived large peptides is sufficient to form a traditional, voltage-responsive sodium channel. In turn, because of the similarities in the sequences and the biophysical and pharmacological properties of sodium channels from different tissues, many of the structures of greatest initial interest (such as the ion pore, voltage-sensing elements, sites of interaction with neurotoxins and anaesthetics) are probably all specified within the large polypeptides. The use of single-channel recording techniques, together with genetically altered channels or with chemically modified reconstituted molecules, should help in the analysis of these essential proteins.

What, then, are some of general structural features of sodium channels that are emerging? First, within the amino-acid sequences of all of the peptides there are four very similar stretches, perhaps reflecting replication of a primordial gene (see figure). These regions (I-IV), each of about 30K, contain all the sequences predicted to form membrane-spanning a-helices. Among these are intriguing periodic sequences in which two hydrophobic residues are followed by an arginine or lysine residue for 4-8 cycles. inviting speculation about gating mechanisms^{13.1} . The intervening sequences. together with the carboxy and amino termini, are polar and not expected to span the membrane. The homologous repeats can be compared with the subunits of the pentameric acetylcholine receptor. suggesting pseudo-subunits on a string which may form a tetramerically ordered bracelet structure (see figure).

The repeat domains are very closely conserved between the electroplax and brain channels, whereas the intervening

and tail sequences are far more divergent, suggesting that the highly conserved biophysical and pharmacological properties can be accounted for largely by domains within the repeat segments. Interestingly, the brain proteins have a large (19–20K) sequence between repeats I and II, containing several consensus phosphorylation sites, that is not present in the electroplax protein. This domain could be involved in modulation, in interactions with smaller subunits or in cytoskeletal attachment. It probably does not participate directly in the 'activity cycle'. In addition, all the peptides are heavily glycosylated; in the electroplax protein sialic acids contribute up to 120 negative charges to the extracellular surface although there may be less in brain and muscle proteins. The new work suggests that for this second ion-channel

prototype the striking departure from the multi-subunit design of the acetylcholine receptor may be more apparent than real.

Also worth mentioning is the discovery of a family of sodium-channel proteins in brain. Some of these may be specific for particular neurones, and some neurones may exhibit multiple species of channel; some channels may be associated with glial cells. If there are banks of genes for ionic channels, their expression in specific cells at appropriate topographical locations must involve regulatory mechanisms that influence and perhaps even respond to the flow of electrical information in neurones and neuronal networks.

Archaean geology

Hungry komatiites and indigestible zircons

from G.R. Edwards and E.G. Nisbet

THERE has been much recent academic interest in the rocks hosting the Kambalda nickel deposit in Western Australia. This is presumably not because salaries are so low that research workers are hoping to find a new mine, but rather because these rocks are forcing a reassessment of one of the most important dating methods in old rocks and are causing us to think again about the processes that occurred when hot lavas erupted through and onto the continental crust 2,700 million years ago'.

At Kambalda, nickel sulphide ores are closely associated with komatiites, lavas with high magnesium contents that generally occur in rocks older than 2.5×10^9 years. The high Mg content implies that komatiites were very hot (up to 1,650°C) when they erupted. Interest in the Kambalda rocks has concerned the age of the komatiites as well as the way in which the sulphide deposits were formed. The debate began when an array of Sm-Nd isotope data from Kambalda was interpreted as evidence that the Kambalda lavas are 3.2×10" years old. Another group interpreted the same data as the result of mixing of material derived from a depleted mantle source with either an undepleted mantle source or material from the lower continental crust'. This group went on to show that Pb-Pb isotopes defined an age of 2.73×10" years, and that Pb isotopes in the rocks may be dominated by the effects of contamination with crustal or surfacederived material.

Compston et al. now provide additional evidence from zircons that not only supports the $2.7 \times 10^{\circ}$ -year estimates but also provides further evidence for crustal contamination. Zircons separated from basalts at Kambalda and analysed for U, Th and Pb isotopes using the SHRIMP ion microprobe have distinct cores with minimum ages ranging from greater than 3,400 to 3,100 million years and surrounded by mantles of younger zircon.

The old zircons are thought to be xenocrysts, partly because there were also zircon mantles and whole zircons with ages less than 2,700 million years in the sample, but also because the zircons are rich in U and Th, suggesting crystallization from felsic magma or recrystallization in felsic rock rather than crystallization from basalt. Mantling of the structural cores of the complex zircons seems to have occurred in two steps: (1) metamorphic recrystallization of the zircons while in their parent rock about 3.1×10° years ago, probably under granulite conditions; and (2) new growth around the metamorphically mantled zircon cores after their inclusion in the mafic-ultramafic magma. From their analysis of younger zircons, Compston et al. suggest the age of extrusion of the lavas is $\leq 2.669 \pm 11$ million years.

What is the ultimate source of the zircons? They are soluble in high-Mg basaltic magmas and would be unlikely to survive a long journey to the surface unless protected by enclosure in small xenoliths. It is also unlikely that new zircons or zircon mantles will grow in zirconium-undersaturated high-Mg basaltic magmas. Nevertheless, zircons are notoriously resistant to melting, so they may survive these processes virtually unscathed and l

the mantles may thus represent an attempt at solid-state re-equilibration by zircons derived from the continental crust. Alternatively, some of the zircons may have been locally derived by assimilation of some of the zircon-bearing interflow sediments. The weight of the isotope evidence thus suggests that there was some contamination of the Mg-rich magmas at Kambalda. Contamination is greatest when heat transfer to the country rock is most rapid, as is the case during turbulent flow in hot, low-viscosity komatiitic magma*.

Ascending hot komatiitic magmas could have thermally eroded the wall rocks of conduits to become contaminated: on eruption, komatiites could have eroded underlying strata. Trace-element evidence⁵ implies that komatiite at Kambalda was contaminated by thermal erosion and assimilation of a mixture of sediment and tholeiites, whereas the high-Mg basalts at Kambalda are the result of up to 25 per cent contamination of komatilte, at depth, by material similar to upper continental crust. As for the nickel sulphide deposits — the reason why so many geologists descended on Kambalda in the first place — Groves et al. concluded from field evidence that thermal erosion occurred, but only where concentrations of sulphide liquid (which has a high thermal conductivitiy) were present at the base of lava channels. Some of this sulphide liquid may have formed from initial thermal erosion of sediments.

What can we learn from all this? The first lesson is that Sm-Nd data from komatiite rocks must be treated with great caution. On the other hand, zircons are extremly interesting if one has an ion microprobe. More generally, the controversy may help to elucidate the mechanisms of komatiite eruption and also the history of the continental crust, which has been sampled by the erupting liquids. Thus some zircon-containing lavas may be useful geochemical probes of the ancient lower continental crust. But some komatiites (especially the most magnesian) may be little contaminated. Perhaps they erupted through conduits that split slightly older komatiite dykes and were erupted on top of komatiite flows. Other komatiitic basalts may be the highly contaminated end-products of the eruption of originally highly magnesian liquids. And as for the nickel deposits, perhaps erosional effects under komatiites are a sign of a nearby sulphide pool.

Antibody diversity

New mechanism revealed

from Frederick W. Alt

THE production of a functional antibody molecule requires the rearrangement of separate gene segments within the germ line of B lymphocytes. Three different segments are rearranged to produce the antigen-binding variable region of the antibody heavy chain. It was thought that no further rearrangements of completely assembled variable-region genes can occur, but two groups^{1,2} report on pages 840 and 843 of this issue that permanent cell lines of the B-cell lineage can exchange most of the body of a rearranged heavy chain variable-region segment with that of an upstream, germ-line variable region gene segment. This novel rearrangement has implications for the effiquences containing 23-bp spacers, D segments are flanked on both sides by 12-bp spacers, and $V_{\rm H}$ segments are flanked downstream by recognition sequences with 23-bp spacers (see figure).

In accord with the 12/23 rule, assembly of the $V_{11}DJ_{11}$ gene occurs by joining of D and J_{11} segments followed by joining of a V_{11} segment to the pre-existing DJ_{11} complex. A consequence of the 12/23 rule is that a pre-formed DJ_{11} rearrangement can be replaced by joining an upstream D to a downstream J_{11} but a $V_{11}DJ_{11}$ rearrangement, once formed, cannot be replaced by joining events to downstream J_{11} segments because direct V_{11} to J_{11} joining is prohibited by the 12/23 rule and all intervening D

a. Scheme for the chromosome after a $DJ_{\rm H}$ join. Recognition heptamers are indicated by open triangles and nonamers by closed triangles; 12- and 23-bp spacers are indicated. The heptamer within the V segment is represented by a dashed triangle. b, A $V_{\rm H}$ to $DJ_{\rm H}$ join; intervening D segments (and 12-bp spacers) are deleted; added N segments are indicated. c, A $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ join; in this case the final assembled V gene consists of the body of $V_{\rm H}2$, a small segment of $V_{\rm H}1$, a 5' N region; a D segment, a 3' N region, and a $J_{\rm H}$ segment. Sizes of the segments not drawn to scale.

ciency of B-cell differentiation and establishes a new mechanism for generating the antibody diversity essential for a competent immune system.

The three germ-line DNA elements of the variable (V) region of an immunoglobulin heavy chain: variable (\dot{V}_{11}) , diversity (D) and joining (J_{tt}) segments, are found on the same chromosome. In the mouse four $J_{\rm II}$ segments are followed immediately upstream by about 12 D segments that are in turn followed at an unknown upstream distance by 200 or more $V_{\rm H}$ segments³. Recombination between these elements is mediated by conserved recognition sequences that consist of a palindromic heptamer (related to the sequence CACTGTG) and an AT-rich nonamer separated by a spacer of either 12 or 23 base pairs (bp). Joining appears to occur only between elements flanked respectively by recognition sequences having spacers of 12 and 23 bp (the 12/23 rule)4.5. This requirement restricts the possible rearrangments as J_{11} segments are flanked upstream by recognition sesegments (12-bp recognition sequences are deleted during $V_{II}DJ_{II}$ assembly).

The novel V_{11} to $V_{12}DJ_{11}$ rearrangment described by Reth et al. and by Kleinfield et al.2 in this issue occurs by a recombination mechanism similar to that used for normal V-gene assembly but uses a recognition heptamer (TACTGTG) found in the 3'-region of most V_{II} genes' (see figure). Notably, this heptamer is identical to that within the recognition sequence flanking the 5' border of most D segments so that although the heptamer 5' of the D segment is deleted after V_{ii} to DJ_{ii} joining. an identical heptamer within the $V_{\rm II}$ gene is now present. The $V_{\rm II}$ gene sequence does not contain an obvious nonamer so the complete upstream recognition sequence is not replaced. However the structure of the V_{11} to $V_{11}DJ_{11}$ recombinants suggests that the internal heptamer mediates site-specific joining, rather than conversion or homologous recombination

Site-specific immunoglobulin-gene recombination mediated by an isolated

heptamer has been shown previously in the light chain? ". In addition, although the TAC and TGT codons of the heptamer encode a conserved Tyr and Cys found in most V-gene segments, Kleinfield et al. note little third-base variation within these residues in V_{11} gene segments, which they believe suggests conservation of the sequence itself. This is perhaps surprising in the light of recent evidence that immunoglobulin recombinase accepts wide sequence variation within the heptamer, at least when it is associated with a nonamer. But Reth et al. indicate that V_0 to $V_{\rm H}DJ_{\rm H}$ joining occurs frequently even though direct $V_{\rm H}$ to $J_{\rm H}$ joining does not occur, perhaps suggesting that the nonamer restricts recombination in the context of the 12/23 rule. Clearly more remains to be learned about the role of recognition sequences.

Assembly of the elements in the V-region gene is not precise and bases can be lost and/or added at the joining point (N regions). The V_{11} - DJ_{11} joint region of the antibody molecule is involved in antigen contact; thus, junctional diversification provides antibody diversity. The studies indicate that V_{11} to $V_{11}DJ_{11}$ joining may allow additional diversification of this important region; sequences left attached from the first V-region provide an additional N-like region (see figure).

Junctional diversification mechanisms have another important consequence for differentiating B lymphocytes. The reading frame of the heavy-chain messenger RNA is determined by the start site for translation at the 5' end of the V_{ii} . Because of random insertion and deletion of bases and the triplet reading frame, approximately 2 out of 3 $V_{II}DJ_{II}$ joins link the V in a different translation reading frame from the J. Such rearrangments are 'aberrant'; they produce heavy-chain mRNA that cannot be translated into a complete heavy-chain protein. Given the inaccuracy of the joining process, in spite of the opportunity for rearrangment on both chromosomes, nearly 50 per cent of differentiating B cells should join both heavychain alleles out of frame'. Previously. such cells were thought to lost from the differentiation pathway, because aberrant $V_{\rm R}DJ_{\rm H}$ joints could not be salvaged. However. Reth et al. demonstrate that permanent pre-B lines that have formed two aberrant $V_{II}DJ_{II}$ rearrangements can rescue the heavy-chain production by $V_{\rm H}$ to $V_{\rm B}DJ_{\rm H}$ recombination. Because of the same imprecise recombination this secondary join can provide a productive reading frame and could make this phase of B-cell differentiation nearly 100 per cent efficient.

The production of complete heavy chains is restricted to a single allele in B cells. Such allelic exclusion appears to result from cessation of V_{11} to DJ_{11} rearrangement when the initial V_{11} to DJ_{11} join

is productive. In the event studied by Kleinfield et al.², the V_{ii} of a productive $V_{11}DJ_{11}$ rearrangement is exchanged with an upstream V_{μ} segment to produce a novel productive rearrangment, indicating that the recombinase is still active in cells with a productive $V_{II}DJ_{II}$. This finding may, at first glance, seem inconsistent with an allelic exclusion mechanism regulating V_{ii} to DJ_{ii} rearrangement. However, current evidence suggests that joining is prevented in cells with a productive $V_{\rm H}DJ_{\rm H}$ rearrangement by limiting access of the recombinase to $V_{\rm H}$ gene segments rather than by turning off recombinase activity'. Recombinase is thought to lose access because transcription of germ-line V_{ii} segments stops in cells that produce complete heavy chains".

Notably, the described V_{II} to $V_{II}DJ_{II}$ recombinations seem to involve proximal $V_{\rm tr}$ segments and it has been shown that the activity of the heavy-chain enhancer in the J_{ii} to \tilde{D}_{ii} intron allows transcription of the proximal unrearranged V_{ij} segment¹²; perhaps by providing access to recombinase. Because allelic exclusion appears to occur in nearly 100 per cent of normal B cells, it seems that V_{ii} to $V_{ii}DJ_{ii}$ joining does not frequently activate expression of both heavy-chain alleles.

 $V_{\rm n}$ to $V_{\rm n}DJ_{\rm n}$ joining may also prevent bias in the development of the heavychain V-region repertoire. Differentiating B cells use the V_{II} segments nearest the J_{II} elements at high frequency to form $V_{11}DJ_{11}$ rearrangements', which limits the spontaneously generated heavy-chain repertoire. But the repertoire of mature peripheral B cells appears to involve all V segments equally. How this occurs is not known, although cellular selection mechanisms have been implicated. Kleinfield et al. suggest that V_{tt} to $V_{tt}DJ_{tt}$ joining may be a means of successively replacing rearranged 3' V segments with more 5' V segments. However, if replacement involves nearest neighbours, as suggested from the data of Reth et al., it is difficult to imagine successive recombination events between hundreds of V genes playing a major role in the process. Final understanding awaits further elucidation of the mechanism and frequency of this process.

Animal behaviour

How great white sharks, sabretoothed cats and soldiers kill

from Jared M. Diamond

PREDATORS that attack large prey enformidable dowed with defensive weapons face a dilemma. If the victim is not incapacitated by the first blow and the predator must continue to engage the victim in order to kill it, the predator itself risks injury. For example, lions are occasionally crippled or killed by zebra, giraffe or rhinoceros prey. Recent studies suggest that two quite different large predators - the great white shark12 and the extinct sabre-toothed cats3 — independently evolved the same solution to this dilemma.

Adult great white sharks (Carcharodon carcharias), the largest living marine fish capable of preying on vertebrates, often feed on seals, whales and other sharks. Common victims in Californian waters are elephant seals, which have formidable teeth combined with a maximum size exceeding that of the shark. The seal is more agile than the shark and is therefore most efficiently hunted by surprise. Timothy Tricas and John McCosker^{1,2} reconstructed the shark's strategy from observations of attacks; scars on seals that got away; and underwater observations (while protected within steel cages) of sharks approaching bait. Bite scars on surviving seals indicate a single massive bite on the l

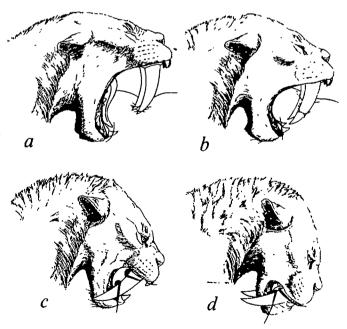

underside of the body. Apparently a shark cruising underwater sees above it the silhouette of a seal basking at the surface, rises undetected towards the seal from behind and below, quickly bites out a large chunk of the seal (the entire biting takes only 1 second), and rapidly retreats to avoid injury. The shark then waits for the seal to go into shock or to haemorrhage before closing in to complete the kill and to feed.

This reconstructed sequence helps one to understand what happens to human victims of great white sharks. Most survivors never saw the shark that attacked them: they merely

felt themselves lifted into the air and then dropped after suffering a single haemorrhaging bite. Victims usually die from loss of blood, not of limbs or vital organs

A similar strategy appears to have been practised on land by extinct sabre-toothed cats of the genera Smilodon and Homotherium³. These lion-sized predators take their name from their very long upper canines (exposed tooth up to 15 cm long in Smilodon). How these weapons were used to kill has been in dispute. The prevalent view until recently was that the upper canines were used to stab or slash the victim while the lower jaw was merely drawn down out of the way. However, closer examination casts doubt on the usefulness of the blunt sabres for stabbing and slashing: they are round-tipped, oval rather than knife-like in cross-section, and barely clear the lower jaw.

Our most detailed information about the preferred prev of sabre-tooths comes from a probable den, Friesenhahn Cave in Texas, where remains of adult plus very small juvenile Homotherium co-occur with scores of baby mammoths, presumably killed by the adult cats and dragged to the den to feed the kittens. Even a baby mammoth could hardly have been killed by the cat at a single blow. Yet it would

How Smilodon used its peculiar anatomy to rip a large piece of flesh out of its prey. Propping its mandible on the prey (a), the cat used its powerful head-depressing muscles to drive in the upper canines (b), rotate the head until the jaws closed (c, d) and pull out a fold of flesh. (Drawing by Mark Hallett. From ret. 3 courtess of the Los Angeles County Museum of Natural History.)

have been suicidal for the cat to continue to grip the baby, as the mother would then have time to crush or impale the cat.

A solution to this dilemma is suggested by William Akersten's anatomical studies3 of remains of Smilodon trapped in the famous La Brea tar pits of Los Angeles. Muscle scars on Smilodon bones show that the muscles for closing the jaws were not especially strong but that the muscles to depress the head by rotating it downwards around the joint with the first neck vertebra were massive (see figures). The chin was flanged, and the jaws opened to the enormous gape angle of 95° to permit the same clearance between the long upper and lower canines as does the 65° gape of modern cats. Akersten suggests the following sequence. A cat ambushes a baby mammoth straying from its mother and uses its powerful fore-limbs to pull down the baby, exposing the abdomen. The cat opens its jaws wide, catches a large fold of flesh between the upper and lower

Cranium and mandible of Smilodon.

canines, wedges the lower jaw firmly against the prey by the chin flanges, and then completes the bite by the head-depressing muscles. It then flees from the approaching mother mammoth and waits for the baby to haemorrhage, die, and be abandoned by its mother.

Yet one more predator has independently evolved a similar solution to the problem posed by a formidable victim. The most dangerous prey of all is an armed man, routinely hunted only by other armed men. Inexperienced soldiers aim for the head or heart, but these small targets are easily missed. "Always aim for the stomach when you shoot" was the advice of an experienced African bush fighter — "it is just as good, because no man can live long after his intestines have been shot away". Nor could an elephant seal or baby mammoth.

Anthropology

The longest human record

from John E. Yellen

THE recent conference* to honour J. Desmond Clark for his contributions to African pre-history provided a unique opportunity to review current ideas about the archaeological record of this continent. African palaeoanthropology is most clearly distinguished by its quest for the first uniquely hominid antecedent: the earliest known hominid fossils derive from the Eastern Rift Valley in Kenya. Evidence for the first million years of cultural development, in the form of stone tools, butchered animal remains and possibly the controlled use of fire, are also limited to the African continent. The first modern humans, Homo sapiens sapiens, were widely distributed in Africa well before their appearance in Europe and the near East and the development of complex societies, in relative independence from those in other parts of the Old World.

Excavations this past summer near Ishango, eastern Zaire, produced stone artefacts associated with faunal remains that are just over two million years old (Jack Harris, University of Wisconsin; Noel Boaz, Virginia Museum of Natural History). In conjunction with stone-tool assemblages from Ethiopia of about the same age, systematic lithic modification must have appeared more than two million years ago. Unfortunately, these artefacts cannot be assigned to specific species.

Arguments were presented that *Homo habilis* was capable of speech (Dean Falk, University of Puerto Rico; Philip Tobias, University of the Witwatersrand). This species had a larger brain than australopithecine forms with prominent enlargement of Broca's and Wernicke's areas, both associated with language in modern humans. These advances appeared at about the same time as the first stone tools.

Whereas most palaeoanthropologists agree that by the mid-Pleistocene Homo erectus had controlled use of fire, there has been no evidence for earlier occurrences. Because charcoal decomposes in tropical environments, African evidence is extremely difficult to obtain. Recently discovered patches of reddened earth in East African sites dates between 1.5 and 1.7 million years ago and which are associated with cultural remains were suggested to indicate much earlier human use of fire (Desmond Clark, University of California; Jack Harris, University of Wisconsin). But palaeomagnetic and thermouminescent analyses failed to provide unequivocal evidence of sediment heating.

*The Longest Record: The Human Career in Africa. Berkeley. California. 12 - 16 April 1986.

The question of early hominid hunting reflects on cognitive ability and social organization. Although animal bones with stone-tool cutmarks provide evidence of carcass use by humans earlier than 1.5 million years ago, it is uncertain whether these remains were acquired by hunting or by scavenging from carnivore kills. If hominids were primarily scavengers, they would be left with the less-choice body parts, which would be reflected in the skeletal elements recovered and the way they were treated to remove remaining scraps of meat. Using such criteria, faunal remains from both Olduvai and Koobi Fora can be interpreted to indicate hunting as cutmarks appear on the primary meat-bearing bones of small bovids which would be unlikely to survive the attention of large carnivores (Henry Bunn, University of Wisconsin).

Also at issue was a large sample of excavated cattle and sheep bones from the Neolithic site of Ngamuriak in southern Kenya. In this butchered assemblage the larger and smaller species are processed differently and a similar pattern is evident in early hominid material (Fiona Marshall, University of California). On the other hand, analysis of the Olduvai Bed I fauna shows 13 cases of overlapping stonetool and carnivore tooth marks. In eight of these the tool mark overtides that made by tooth, indicating human scavenging (Pat Shipman, Johns Hopkins University).

Recent work on the eastern margin of the Kalahari Desert shows a pattern of increasing complexity and hierarchical organization which, in effect, set the stage for the emergence of the Zimbabwe culture (James Denbow, National Museum of Botswana. The Venda, who are among the lineal descendents of Zimbabwe people, use variation in motifs on compound walls to denote status. Direct counterparts exist in Zimbabwe period stone-walled structures and, by application of Venda data, it has been possible to reconstruct a five-level hierarchy which extended from heads of individual households to the divine national leader (Thomas Huffman, University of the Witwatersrand). Because the gradual evolution of this system can be traced through time it is highly unlikely that the final structure was a direct results of outside stimulus (trade with Indian Ocean powers) but more probably derived from indigenous roots.

Neurophysiology

Parallel channels and redundant mechanisms in visual cortex

from N.V. Swindale

ALL too rarely, pharmacologists come up with a drug that interferes selectively with a particular pathway or a single welldefined function of the nervous system. Ideally the drug should be easily administered, specific and reversible, but such combinations are not often achieved. One molecule that does seem to satisfy these criteria is the glutamic acid analogue 2-amino-4-phosphonobutyric acid (APB) which has been studied by P.H. Schiller and collaborators and whose latest work is reported on page 824 of this issue¹. APB blocks the function of a class of retinal ganglion cells, and it is hoped that it will help to determine to what extent the visual system functions as an integrated whole or whether its differrent components are capable of some degree of independent function.

The pathway from retina to brain is divided into parallel channels, each selective for different attributes of the image, such as light intensity, colour and spatial frequency. Each channel consists of neurones of two types, ON and OFF, the former responding only to light levels that are greater than the local average in the image and the latter responding (by an increase in firing rate) to levels that are less than the local average. Thus, ON channels carry information about bright spots or areas in the image and OFF channels do the reverse. This division of labour, which resembles that of the pushpull output stage of an amplifier probably has more than one advantage: it allows cells to have low levels of activity when the retina is in darkness or uniformly illuminated, reducing metabolic requirements, and it effectively doubles the dynamic range over which neurones can signal information about light levels in the retinal image.

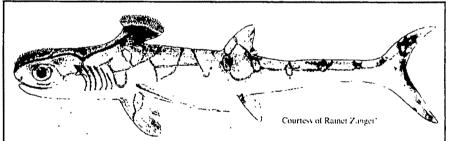

The separation between ON and OFF pathways occurs at the synapse between the rod and cone photoreceptors and bipolar cells, the earliest stage in the visual pathway. All photoreceptor cells hyperpolarize in response to light, but the bipolar cells to which they are connected are of two types: ON bipolars that depolarize when the photoreceptor to which they are connected hyperpolarizes, and OFF bipolars that hyperpolarize when the photoreceptor hyperpolarizes. If APB is applied to the retina it hyperpolarizes the ON bipolars, silencing cells post-synaptic to them². The action of APB appears to be the same in retinas from all species of vertebrate, and is specific to all classes of ON channel.

One of the first observations made with the drug' was that it did not abolish the antagonistic centre-surround organization of either retinal cells or lateral geniculate nucleus cells to which the retina projects. This means that the inhibitory actions involved in generating the surround must occur entirely within the OFF pathway. The same is probably true for the ON pathway. ON and OFF channels thus remain separate in the retina and the lateral geniculate nucleus, and the pathways do not converge until the inputs reach the visual cortex.

The ability to disable half of the visual system in this way raises obvious questions. Can each half function on its own and, if so, how well? Because an edge normally has both light and dark components, it might be thought that the detection of edges and their orientation (a function of the visual cortex) will depend on the proper functioning of both ON and OFF channels. Blocking the ON channels by applying APB to the retina might be expected to interfere seriously with vision. But it appears that, although APB does have some deleterious effects, they are much less than had been supposed.

The carefully controlled experiments on awake monkeys reported in this issue show that, when treated with APB, the animal cannot detect a light coming on. although it can still detect the onset of a dark spot. Perhaps more relevant is that many visual functions are relatively unimpaired by APB. For example, the report shows that monkeys treated with the drug have qualitatively normal stereopsis when tested with random-dot stereograms and can detect apparent motion in randomdot kinematograms. Both these tasks are normally regarded as rather severe tests of visual performance. Other studies show that cortical neurones in APB-treated animals, although lacking in ON responses, still possess orientation and direction selectivity.

Although interactions between ON and OFF channels are not necessary for the generation of many neuronal-response properties, they do not prove that such interactions do not occur, or that they have no important functional role. A really careful comparison of the properties of cortical cells between normal and APB treated animals has vet to be carried out, and strong interactions between ON and OFF inputs to the cortex are known to exist (see, for example, ref.4). It seems

New discoveries of some remarkable Lower Carboniferous fish1-5 show that they had vast toothed spines apparently suspended directly above their heads. Stethacanthus, a 1-m-long shark, now known from nearly complete specimens from Scotland and Montana¹⁻³, had a remarkable spine shaped like a shaving brush just behind its head. The spine stands nearly vertical and is topped by dozens of small teeth. It is clearly an unwieldly structure and must have had an important function. The spine was present in both males and females, and Zangerl' suggests that it was used to scare off potential predators: Stethacanthus had a patch of teeth on top of its head as well and, when partially buried in the mud, the two toothed areas would have mimicked a vast gaping mouth, as if of some giant predator. The figure illustrates the possible appearance of the fish3.

A second stethancanthid, Falcatus⁴, is a small shark up to 14.5 cm long and has a long, shelf-like spine extending from roots deep in the muscles of the 'shoulder' region to run over the head, like a sunshade. The spine is in two parts, the fixed base and the horizontal portion which slots on to it, and is present only in sexually mature males. Lund' suggests that male Falcatus sharks aggregated before the breeding season for display-courtship rituals. The third complete Stethacanthid shark, Damocles', is also small (up to 20 cm long) and differs from Falcatus in having a simpler spine with many sharp teeth. Michael J. Benton

very likely that in many cases these interactions must be involved in generating orientation selectivity (for example, in cells that are believed to receive inputs from only a single ON centre and a single OFF centre cell, side by side).

Other recent results support the idea that orientation selectivity is produced by more than one mechanism, and in more than one location in the visual cortex. Inactivation of the A layers of the lateral geniculate nucleus (a major source of visual input to the cortex) abolishes all responses in the middle layers of the cortex, but leaves orientation selectivity in the upper cortical layers unimpaired. Conversely, inactivating the upper cortical layers by cooling leaves orientation selectivity in the middle layers of the cortex intact⁶. It had previously been thought that orientation selectivity in the upper layers was merely a passive reflection of the orientation selectivity of their inputs from the middle layers of the cortex but these results^{5,6} mean this cannot be entirely true.

The idea that many cortical properties are generated redundantly, by interactions both within and between different parallel afferent pathways to the cortex, in

different cortical layers and perhaps by different mechanisms, has several attractions. Redundancy of mechanism would render the brain less sensitive to pathological or experimental damage to particular subdivisions in the nervous system. Inadequacies in any one mechanism might be compensated for by some corresponding advantage in another. More than one type of processing algorithm is needed to account for other aspects of visual performance, such as stereopsis7, and perhaps it is easier to evolve several relatively crude neural mechanisms that work in parallel to achieve a particular goal than to evolve just one especially effective one. Single elegant solutions to particular problems may not exist in the brain: quantity, rather than quality, of mechanism is what counts.

Chiral chemistry

Asymmetric epoxidation gives organic chemists a hand

from Martin Bryce

THE asymmetric epoxidation of allvlic alcohols is one of the most innovative reactions introduced into organic chemistry in modern times1. The tremendous potential of this reaction was recognized soon after its discovery six years ago by Sharpless and Katsuki². However, as the target molecules for organic chemists become ever more complex, several years' work may be needed to complete intricate, multistep syntheses, and it is only within the context of such challenging synthetic chemistry that the true value of a new reaction can be seen. Recently, Sharpless and colleagues have made an important improvement in the reaction conditions3, and it is now clear that the Sharpless époxidation has come of age as a practical method for the introduction of chirality into a wide range of organic molecules.

To understand the significance of this reaction we must be aware that the organic molecules of life are chiral (that is, like right and left hands, the molecules are mirror images of each other) but they are not identical because they are non-superimposable. From the most primitive to the most highly developed organisms, the life processes at the molecular level depend critically on this chirality. A molecule which on further substitution can become chiral is termed prochiral. A chiral reagent will distinguish between the faces of a symmetrical, prochiral structure giving rise to unequal amounts of chiral products, whereas an achiral reagent will show no selectivity. For example, reduction of a prochiral amino-acid precursor (see figure: structure 1) by an achiral reagent such as hydrogen can occur with equal probability from each of the two faces of the C=N bond, giving rise to a 50:50 mixture of the two chiral forms of the amino acid (structure 2); there will be no selectivity. These chiral products are termed (S) and (R) enantiomeric forms. However, the two faces of prochiral molecule (structure 1) are not the same to a chiral reagent, such as an enzyme, which will attack one side to the virtual exclusion of the other. Indeed, for the most part, enzymes produce only the amino acids having the (2)-(S) configuration (see figure).

Organic chemists strive to develop highly efficient methods of synthesizing pure enantiomers of organic compounds,

both for academic interest and for commercial application, for example in the fields of pharmaceuticals and pesticides where, frequently only one enantiomer of a compound is biologically active. Thus, asymmetric hydrogenation using chiral catalysts has become a well-established laboratory procedure over the past decade4. Until recently, however, the counterpart of this reaction, asymmetric oxidation, has met with little success.

The answer has proved to be the Sharpless reaction, which is based on both organic and inorganic stereochemistry

and uses reagents that are either commercially available or easy to prepare. The reaction, which involves treatment of an allylic alcohol (see figure: structure 3) with a mixture of titanium tetra-isopropoxide, t-butyl hydroperoxide and diethyltartarate (DET) (structure 4) to give an epoxy alcohol (5), can be controlled, with (5a) or (5b) forming in more than 95 per cent enantiomeric excess. Thus, remarkably, the reaction approaches the stereoselectivity of an enzyme system and even surpasses most enzymes in the variety of substrates (groups R, R' and R" in structure 3) that will react. In a recent improvement³, the addition of molecular sieves to the reaction mixture enables as little as 5 moles per cent of titanium tartrate complex to be used to ensure high enantioselectivity of the epoxidation.

Sharpless considers that the titanium metal catalyst serves to organize the epoxidizing agent (t-butyl hydroperoxide). the chiral-inducing agent (diethyl tartrate) and the substrate (the allylic alcohol) into such geometry that reaction at one face of the double bond is greatly preferable to reaction at the other face. In the key step, the epoxide oxygen is always delivered to the same face of the olefin for reaction involving a specific tartrate isomer (structure 4a or 4b). If the allylic alcohol (structure 3) is represented by the stereochemical model (6), the oxygen is delivered from the bottom face using L(+) DET and the top face using D(-) DET, to give chiral epoxy alcohols (5a) and (5b), respectively.

The ability of epoxy alcohols to retain chirality while undergoing a wide range of subsequent transformations has enabled the Sharpless epoxidation to be incorporated into numerous multistep syntheses of chiral compounds (see ref. 1 for a recent review). For example, Mori's synthesis of structure 9, the sex pheromone of the beetle Hylecoetus dermestoides (a pest of European hardwood and softwood trees) starts from prochiral allylic alcohol (structure 7). This alcohol was transformed by the Sharpless reaction into epoxy alcohol (8) which contains the required stereochemistry for elaboration into the desired chiral product (9) (see figure: scheme 1).

A class of pharmaceuticals where improved synthetic routes incorporating the Sharpless oxidation have been described are leukotrienes, important in various inflammatory diseases. A new synthesis of leukotriene A (structure 12) involves, as a key step, formation of chiral epoxide (11) from prochiral allylic alcohol (10) (see figure: scheme 2).

The Sharpless epoxidation procedure also provides easy access to rare monosaccharides which are important structural components of certain natural products and are also valuable synthetic intermediates. For example, epoxy alcohol (structure 13) can be converted into hexose derivative (14) which is a component of the antibiotic olivomycin A.

These examples show how important asymmetric epoxidation reactions can be for those who wish to make chiral molecules with high enantiomeric purity by simple and reliable procedures.

Cytoskeleton

New views of the red cell network

from Velia M. Fowler

THE elaborate schemes of the molecular anatomy of the erythrocyte membrane skeleton that have evolved over the years' are based almost exclusively on studies of the properties and associations of purified proteins in vitro. Attempts to analyse the structure of the membrane skeleton in situ have been impeded by the enormous density of the components, particularly spectrin, in the plane of the membrane. Several groups'h, most recently Steck and his colleagues, have succeeded in artificially spreading out the spectrin network without (apparently) disrupting the linkages holding it together. Far from being ". . . an anastomosing framework woven by a myopic fisherman", the membrane skeleton is organized as a strikingly regular lattice in the plane of the membrane.

Five to seven long, thin filaments (about 180 nm long), whose morphology corresponds to purified spectrin tetramers, are attached by their ends to junctions comprised of short, stubby actin filaments (33-37 nm long), thus generating a series of polygons, mostly hexagons, in which the sides are spectrin molecules and the vertices actin filaments (see figure)6.7. The latter appear thicker than normal actin filaments, implying that additional proteins are associated with them (see below). There is even a glob near the middle of the spectrin tetramers that is in the right place to be the ankyrin-band 3 membrane attachment site for spectrin". What is so satisfying about these negatively stained images of the spread membrane skeleton is that they are completely consistent with the models inferred from work with purified proteins.

The surface area of the spread membrane skeleton is calculated to be about 9-10 times that of the unspread membrane, indicating that the fully extended spectrin molecules (about 180 nm) are around three times longer than necessary to span the distance between adjacent actin filaments in the unperturbed membrane (about 60 nm)". It is an interesting question whether the spectrin tetramers in the unperturbed membrane are actually folded or coiled into a conformation with a more compact structure, or whether they are simply looped passively from one actin filament to the next so as to accommodate the surface area of the lipid bilayer itself. This distinction could have implications for the molecular mechanism of ervthrocyte shape transformations and for the viscoelastic properties of the erythrocyte

One source of support for the second

model is the observation that images of the spread membrane skeleton of reticulocytes are practically indistinguishable from those of the mature cell with respect to the essentially hexagonal pattern of the lattice (S.-C. Liu and J. Palek, personal communication), although the surface area is about three times greater in the one than in the other .

Thus, it seems that the reduction in membrane surface that accompanies maturation takes place without major changes in the organization of the membrane skeleton. Because analogues to spectrin, ankyrin and protein 41 arc present on the plasma membranes of nonerythroid cells', it will be interesting to

Negatively stained preparation of the spread crythrocyte membrane skeleton (from ref. 4)

see if the organization of the membrane skeletons in these cells uses similar principles to achieve local changes in membrane area during some cell movements.

Complexes that evidently represent isolated lattice vertices and that consist of about six spectrin 'legs' extending from a body containing a short actin filament have recently been isolated contain protein 41, which promotes complex formation, and protein 49, which is thought to be bound to actin (see refs 2-4). Tropomyosin may also be associated with the junctional complexes in situ, as this protein is present on the membrane in sufficient quantity to satisfy the binding capacity of the actin

A dimeric calmodulin-binding protein of relative molecular mass (M) 97,000 103,000 has just been discovered in the membrane skelton. It is also thought to be associated with the junctional complexes. as there are about the right number (30,000 copies) per cell, that is I dimer per filament of 16 actin monomers. But it is not yet known with which of the proteins in the membrane skeleton it is associated Immunolocalization of these various proteins in the membrane skeleton will be necessary to ascertain whether they are indeed associated with the junctional complexes that form the vertices of the spectrin lattice.

Why should the molecular substructure of the junctions in the erythrocyte membrane skeleton be so complex? An attachment site for about six spectrins would need only a small actin filament containing six actin monomers, along with six molecules of protein 4.1. However, a junctional complex composed only of spectrin, protein 4.1 and actin would not be self-limiting because of the propensity of actin to polymerize into long filaments under physiological conditions.

Restriction of actin-filament length by the accessory proteins mentioned above (alone or in combination) could serve to regulate the number of spectrin molecules attached to the junctions and thus specify the surprisingly regular lattice structure of the network. Some slippage in filament length regulation could easily account for variation in numbers of spectrin molecules attached to the junctions 3-7.

An apparent paradox is that although the stoichiometry of spectrin-protein 4.1 binding to actin filaments in vitro is equimolar, there are only about six spectrin molecules attached to any one of the 13- to 15-monomer-long actin filaments⁵⁻⁷: Because tropomyosin binds in the two grooves of the actin-filament helix without restricting filament length¹³, and protein 4.9 bundles actin filaments in vitro¹⁵, we still have no explanation for the actinfilament length restriction that is observed in situ.

In addition to ensuring the correct assembly of the membrane skeleton, it is conceivable that changes in the structure of the junctional complexes mediate the calcium- and ATP-dependent discocyte

-echinocyte shape transformations of erythrocytes. A calcium- and calmodulindependent protein kinase activity has just been identified in erythrocyte membranes which phosphorylates both protein 4.1 and an M. 100,000 doublet of polypeptides in the membrane skeleton¹⁶, which could well represent the M, 97,000/103,000 calmodulin-binding dimer¹⁴. Protein 4.1, as well as protein 4.9 and the same(?)' M. 100,000 doublet are also phosphorylated by a recently identified protein kinase C activity in the erythrocyte 16-20. In addition. proteins 4.1 and 4.9 are phosphorylated by a cyclic AMP-dependent kinase, but at different sites from those phosporylated by protein kinase C211

A recent observation by Tao and coworkers21 provides evidence that these phosphorylations influence the organization of the membrane skeleton. The affinity of protein 4.1 binding to spectrin in vitro is reduced by about fivefold on phosphorylation of protein 4.1 (but not spectrin) by a purified cyclic AMP-independent kinase from red cells21. It is also suggestive that the cyclic AMP phosphorylation site on protein 4.1 has just been found to reside in a spectrin-binding domain of M, 8,000 (ref. 22). Undoubtedly, these observations are only a taste of things to come, and many of the protein associations in the erythrocyte membrane skeleton may prove to be dynamically regulated in response to physiological signals in vivo.

Glaciology

Frozen news on hot events

from Claus Hammer

ICE CORES from Antarctica and Greenland provide information on the number and dates of violent volcanic eruptions and their contributions to the upper atmospheric composition of trace substances. Intérpretations of the ice-core records, particularly deductions about the influence of local eruptive activity and the varying meteorological and climatological conditions during trace-substance transfer from the volcano to the ice sheets, are difficult, partly because the techniques used in various studies have not been coordinated. A recent article by R.J. Delmas et al. (J. geophys. Res. 90, 12; 1986) concludes that the techniques used to detect volcanic signals in ice cores are all in essential agreement. Although the visible fine-ash (tephra) layers observed in antarctic ice cores must be considered separately from other data, the conclusion of Delmas et al., that the sulphuric acid record in the cores reveals remote and violent eruptions, remains unchanged.

Delmas et al. analyse ice cores from various sites in Antarctica, both from coastal regions of high precipitation and central sites that show very low annual accumulation. They look at acidity, electrical conductivity of melted ice samples and ionic composition during the past 200 years. The lack of historic data on eruptions in the Antarctic area limits the analysis, but the authors are able to conclude that local volcanic activity in the Antarctic contributes only little to the ice-core chemistry. The fallout of fine ash is only significant close to local volcanoes (some 200 km) and the SO, and/or HCl from such eruptions is apparently washed out before reaching the more central parts of Antarctica, where the volcanic acid signal is particularly clear. (This conclusion does not, of course, cover violent or substantial regional activity.) Thus the major increases in sulphuric acid concentration of the central Antarctic ice is caused by remote volcanic eruptions. Transportation of the volcanic products occurred mainly via the stratosphere, although some arrived via the upper troposphere: NH, neutralization is virtually absent. Transfer from the site of eruption to the ice sheet during glacial times has yet to be quantitatively assessed.

The conclusions of Delmas et al. provide a global perspective and agree with the results obtained from the Greenland Ice Sheet (see, for example, Hammer, C.U., Clausen, H.B. & Dansgaard, W. Nature 288, 230; 1980). The Antarctic ice cores provide information on past volcanic eruptions south of 20° N, whereas Greenland registers eruptions north of 20° S, so data series from the two ice sheets offer global coverage and overlapping information.

To establish a detailed and well-dated ice-eruption record; to estimate from the chemistry of the cores the influence on atmospheric composition; and to identify the geographical sites or zones of the eruptions are formidable tasks which will require not only a good deal of optimism but also new and faster techniques for analysing the details of the chemical composition of the several thousand-metre-long ice cores. More data from the smaller ice caps, for example in the Canadian arctic, are needed.

Claus Hammer is at the Geophysical Institute, University of Copenhagen, Haraldsgade 6, 2200 Copenhagen N. Denmark.

SCIENTIFIC CORRESPONDENCE

Table 1 Radioisotopes identified from air filters

Chernobyl fallout on Ioannina, Greece

SIR-We have measured the y-ray spectrum of the fallout from the Chernobyl nuclear reactor accident at Ioannina, located in northwestern Greece, nearly 1,500 km south-west of Chernobyl. We have examined air filters collected every 24 h since 29 April to monitor the yradiation activity, using an intrinsic germanium high-resolution detector, shielded to reduce background. The fallout probably reached Ioannina between 1 and 2 May, and the activity peaked on 5 May. After that we noticed a reduction of the air contamination, mainly due to local

Figure 1 shows a typical γ-ray spectrum from one of our filters, the activity of which was measured three times at monthly intervals to estimate the halflives of the radionuclides present. From a number of spectra, 14 different nuclides were identified by their energy spectra and half-lives and 9 additional peaks in the spectral region between 50 and 800 KeV remain unidentified.

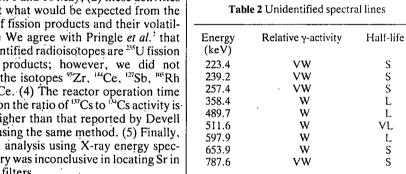

In Table 1 the activity of each of the most prominent radioisotopes is characterized as very strong (VS), strong (S), weak (W) or very weak (VW), and the respective half-life as very long (VL), long (L) or short (S). The ¹³¹I activity is defined 'strong' and its half-life as 'long'. Table 1 also lists the masses of fission decay products generated in the reactor'. Table-2 lists the energies of the unidentified lines.

From our air-filter measurements we conclude that: (1) the relative activities for the most prominent isotopes remained unchanged during most of the period

•			•
Isotope	Relative γ-activity	Half-life	Mass of fission products (mg MW ¹ day ¹)
⁹⁵ Nb	vw	VL	0.33
⁹⁹ Mo	W	S	107.0
¹⁰³ Ru	VS	VL	
	ι		65.4
¹⁰⁶ Ru	W	VL	
^{129m} Te	VW	VL	
			15.7
¹³² Te	S .	S	
131 I	S	L	5.86
132 _I	S	S	
¹³⁴ Cs	S	VL	
¹³⁶ Cs	VW	, L	90.4
¹³⁷ Cs	S ·	, VL	
¹⁴⁰ Ba	W	L	38.6
¹⁴⁰ La	W	S	39.8
¹⁴¹ Ce	VW	VL	86.0

between I and 10 May; (2) these activities are not what would be expected from the mass of fission products and their volatility. (3) We agree with Pringle et al.2 that the identified radioisotopes are 235U fission decay products; however, we did not locate the isotopes 95Zr, 144Ce, 127Sb, 1018Rh and ¹¹³Ce. (4) The reactor operation time based on the ratio of 137Cs to 134Cs activity is 15% higher than that reported by Devell et al.' using the same method. (5) Finally, a trace analysis using X-ray energy spectrometry was inconclusive in locating Sr in our air filters.

The extreme conditions in the reactor core after the accident make it hard to know in what chemical compounds the radioisotopes appear in the radioactive cloud. Unfortunatly, information about core conditions before and during the accident is not yet available to us, and therefore we cannot verify our assumption

that the surprisingly high proportion of non-volatile nuclides (such as "Ru) and the absence of volatile nuclides reflect the chemical compound which hosted the nuclides at the time of release to the atmosphere.

The origins of the Earth's oceans

Six—Several mechanisms have been proposed for the origin of the Earth's oceans. such as the degassing of crustal rocks over geological time and the formation of impact produced atmosphere, including water, by accretion of planetesimals2 early during the Earth's formation. The available evidence suggests that sizeable oceans were present early in the Earth's history3 and that the early Solar System

was fractionated, with nickel-iron and carbonaceous chondrites largely contained in the volume on the sunward side of Mars's orbit, and gases (hydrogen, helium, methane, water) and some carbonaceous chondrites in the volume from Jupiter's orbit outward.

Present theories on the origin of the oceans fail to account for the fact that Venus, a planet very similar to Earth in size and composition, has no surface water and only small amounts of atmospheric water. This could be explained by assuming that, early in its history, Earth collided with an ice moon approximately 900 to 950 miles in diameter, which could have furnished all the water presently on Earth. This collision, obviously a rare event, would have provided for rapid cooling of the Earth's crust, prevention of a runaway greenhouse effect by the absorption of most atmopsheric CO₂, and rapid evolution of life. This theory is also in accord with the fractionated nature of the early Solar System.

Frequency of dizygotic twinning

SIR—From the assumption that ovulation with intercourse leads to a live birth with probability 1/4 for each egg, double ovulation may be expected to lead to dizygotic twin births with probability 1/16. From that realtionship, J. Diamond (Nature 320, 488; 1986) suggested that an observed frequency of 4.9% dizygotic twin births among the Yoruba implies a double ovulation frequency of 16 times 4.9, or 78%.

M. Sipser (Nature 321, 570; 1986) pointed out that this suggestion is incorrect. On the simplest set of assumptions, double ovulation will lead to no birth in 1/16 of cases, to a single birth in 5/16 of cases, and to dizygotic twins in 1/16 of cases. From those relative frequencies, Sipser asserted that an observed frequency of 4.9% dizygotic twin births implies a double ovulation frequency of 7 times 4.9 or 34%.

In fact the relationship between the frequencies of double ovulation and of dizygotic twin births cannot be expressed by a constant factor. When the frequency of double ovulation is extremely low, the single births that result from double ovulation can be ignored, and the observed frequency of dizygotic twin births must be multiplied by 4 to obtain the frequency of double ovulation (single births=1/4 of single ovulations; dizygotic twin births= 1/16 of double ovulations). When the frequency of double ovulations is high, the single births that result from double ovulations must be taken into account, and the factor rises. In the extreme case, if the probability of double ovualtion were 1.0, by of the births would be dizygotic twins; the factor would be 7. Sipser's comment is valid only for this case, which is of no biological significance for any known human population.

The general expression to be used is F=T/(pT+p-T), where T is the fraction of dizygotic twin births, p is the probability per egg of a live birth, and \vec{F} is the fraction of double ovulation. When p is assumed to be 0.25, this becomes F=4T/(1-3T).

In any real case, the factor [4/(1-3T)] is much closer to 4 than to 7. For the dizygotic twinning frequencies that occur in the human populations tabulated in Diamond's article (0.22% to 4.9%) the appropriate factors are between 4.03 and 4.7. In the Yoruba population the frequency of dizygotic twin births was 4.9%, and the estimated frequency of double ovulation, if $P = \frac{1}{4}$, is 23%.

How to abbreviate recombinant genes

SIR-We are all aware that recombinant DNA technologies have generated tremendous progress and spawned a literature that seems to grow exponentially. Unfortunately a custom is developing of using the abbreviation rDNA to refer to the hybrid molecules formed by uniting two or more heterologous DNA molecules; this leads to confusion, since rDNA has long been used to refer to ribosomal DNA. The abbreviation rRNA and r proteins are also in common use with r again meaning ribosomal.

To avoid confusion. I suggest the use of rt for recombinant and that editors of journals start insisting on a differentiation between rDNA and rtDNA and rRNA and rtRNA.

ROBERT C. KING

Northwestern University, Evanston. Illinois 60201, USA

A system of nomenclature for murine homoeo boxes

SIR—There is at present a considerable degree of confusion amongst workers on mammalian homoeo boxes because each group has tended to select a different system of nomenclature. It is now very difficult to follow the literature appropriately. To help avoid this confusion we would like to offer the following system.

A unifying nomenclature for murine homeo boxes should consider the chromosomal location and the number of boxes on a chromosome. Clusters of boxes should preferably be numbered consecutively and in the direction of transcription. The two known clusters are probably transcribed in one orientation only and do not contain additional boxes. Thus, at least these two would be numbered consecutively from the 5' to the 3' end of the cluster. The nomenclature should further allow a logical naming of newly discovered

We suggest the new prefix 'Mox', followed by two numbers: the first one giving the chromosomal location, the second identifying an individual box on the respective chromosome. This procedure leads to the following nomenclature for a selection of published murine homeo boxes:

Proposed name	Original designation	Chromo- some	Ref.
Mox 1.1	Mo-en.1	1	1
Mox 6.1	m6	6	2
Mox 6.2	m5	6	3 3
Mox 6.3	m2	6	3
Mox 6.4	HBT-1, MH3.		
-	Hox 1.3.	6	4.5
Mox 6.5	Mo 10, Hox 1.4.	6	6
Mox 6.6		6	
Mox 11.1	Hox 2.4	11	7
Mox 11.2	Hox 2.3	11	7
Mox 11.3	Hox 2.2	11	7
Mox 11.4	Hox 2.1, H24.1,		
	Mul '	11	7-9
Mox 15.1	Hox 3, m31	15	10,11

For new isolates, we suggest the following, assuming that the description of these boxes will include the information on chromosomal location and occurrence of clusters. In this case, we propose the term 'Mox', followed by the chromosome number, a period and the lowest unused number on the respective chromosome for the most 5' box of a new cluster.

After a box has been designated in this way, the name should be kept unchanged even if new information reveals a violation of the consecutivity rule. Non-mapped isolates (from cDNAs, for example) have to obtain a preliminary designation.

A litany of folly

Walter Gratzer

Diamond Dealers and Feather Merchants: Tales from the Sciences. By Irving M. Klotz. *Birkhäuser:1986. Pp.120.* \$24.95.

"As to the opinion which explains the putrefaction of animal substances by the presence of microscopic animalcula, it may be compared to that of a child who would explain the rapidity of the Rhine's current by attributing it to the violent movement of the numerous mill wheels at Mainz." The view is that of Justus von Liebig (echoed some time later by, I think, James Thurber, who held that wind is caused by trees waving their branches), and the child in question is Pasteur. Or try this: "Recently I pointed out that deficiencies in fundamental chemical knowledge and the lack of a good liberal education characteristic of many professors is responsible for the current decline in chemical research . . . If anyone thinks my concerns are exaggerated, he should read, if he can stomach it, a recent monograph of a Mr van't Hoff, entitled The Arrangement of Atoms in Space, a book swollen with infantile foolishness." That egg was laid by the great Hermann Kolbe, the first man to synthesize a organic compound, acetic acid, from its elements. In Diamond Dealers and Feather Merchants. Professor Klotz has assembled a wonderful collection of such philippics in his exploration of how these thunderous gaffes come to be perpetrated — hostages heedlessly offered to fortune by those best placed to know better.

Perhaps success, like power, tends to corrupt; Ambrose Bierce in *The Devil's Dictionary*, ever a sound guide to human nature, encapsulates the matter thus: "Intolerance is natural and logical, for in

"Klotz suggests that the strange passions that cloud the judgement and take the reason prisoner can express themselves as much in credulity as in obduracy."

every dissenting opinion lies an assumption of superior wisdom." The uninhibited ferocity and vindictiveness with which academic vendettas were publicly conducted belong of course to a bygone age of polemic. The heavy, snarling sarcasm, the pseudonymous lampoon on the rival's work, have given way to a little discreet disparagement in the intimacy of the grant committee; but the results are similar and it is probably an inalienable part of the scientific process. Max Planck said that radical scientific innovations do not prevail by overcoming prejudice, but rather through the eventual demise of their

opponents, to make way for a new generation of scientists whose prejudices have not yet hardened.

Klotz suggests that the strange passions that cloud the judgement and take the reason prisoner can express themselves as much in credulity as in obduracy. Chauvinism and political engagement play a part in two spectacular scientific debacles that he chronicles with relish, but not without compassion: N-rays were named after the city of Nancy by the respected French physicist, Blondlot, Klotz surmises that Blondlot's formative years would have been darkened by the defeat and disintegration of the Second Empire and the loss of much of Lorraine, which brought the German border almost to Nancy. This must have inflamed the rivalry, already intense, between French and German science. In addition, Blondlot was probably still grieving at the turn of the century that the discovery of X-rays had eluded him.

N-rays were an electromagnetic radiation emitted from electric discharges and many other sources, such as hot metals. They were taken up with fervour by French physicists, chemists and indeed biologists, for it soon emerged that nerves, muscles and even enzymes were abundant emitters. By 1904 the ratio of papers in the Comptes Rendus on N-rays to those on X-rays was 53:3. The outside world was more cautious and the end came when the great American spectroscopist, farceur and eccentric, R.W. Wood (the man who trained his cat to clear the cobwebs from the 40-foot optical path of his spectrograph), visited Blondlot's laboratory to observe the measurement of wavelengths in the N-ray spectrum, dispersed by an aluminium prism. The room being dark, Wood adroitly trousered the prism, with no detriment to the process of data collection. Wood spared no feelings when he subsequently described the events in Nature. J.A. Le Bel expressed what many French scientists must have felt: "What a spectacle for French science that one of its distinguished savants determines the position of lines in the spectrum while the prism sits in the pocket of his American colleague."

it is probably an inalienable part of the scientific process. Max Planck said that radical scientific innovations do not prevail by overcoming prejudice, but rather through the eventual demise of their Klotz seeks a parallel between the N-ray affair and the curious mirage, half a century later, of polywater — an associated form of water reported by the Russian surface physicist. Boris Derja-

guin, to form in fine silica capıllaries -- for here too political prejudice may have exerted a baleful influence. J.D. Bernal. who was preoccupied at this time with the structure of water, must, so Klotz believes, have badly wanted Soviet science to come up trumps. (He continued, for instance, to support Lysenko long after the truth had come out in all its squalor.) Bernal did in the event jump off the polywater bandwagon before that vehicle careered over the precipice, taking many reputations with it. Joel Hildebrand, the Methuselah of physical chemistry who published his last paper at the age of a hundred, seemed in no doubt from the outset. "Water and silica." he wrote, "have been in intimate contact in vast amounts for millions of years; it is hard to understand why any ordinary water should be left." Another physical chemist. R.E. Davis, put it succinctly "We must conclude that all polywater is polycrap and that the American scientists have been wasting their time studying the subiect". In retrospect it seems that most of these scientists could have believed in polywater only because they wanted

"Chauvinism and political engagement play a part in two spectacular scientific debacles that Klotz chronicles with relish, but not without compassion."

polywater to exist. Derjaguin accepted earlier than many that he had been wrong, and emerged with dignity from the reeking shambles.

Klotz concludes with some examples of credulity and ignorance to make your toes curl. Thus: "From experience with non-science college students. I know that the majority predict that if a silver dollar and a silver dime are simultaneously dropped from the top of the Sears Tower the former will hit the ground first. An even larger fraction when asked whether a two-inch line or a one-inch line has more points will vote in favour of the former: the remainder exercise their democratic privilege of not voting. The general public would overwhelmingly endorse [this] view." I understand the flat-Earthers are still among us, satellite pictures notwithstanding: common sense lives.

Professor Klotz's name is familiar to all protein chemists, and generations of science students were brought up on his celebrated textbook of chemical thermodynamics. He now reveals himself as a writer of wit, wisdom and originality in a different genre. This admirable little book will give much pleasure.

Looking beyond creature comforts

Marian Stamp Dawkins

Laboratory Animal Husbandry: Ethology, Welfare and Experimental Variables. By Michael W. Fox. State University of New York Press: 1986. Pp.267. Hbk \$39.50; pbk \$9.95.

I MUST confess that most books on animal welfare give me a sinking feeling even before I read them. I have a prejudice, no doubt grossly exaggerated and unrelated to the real world, that there are only two types of book about this subject. The first treats animals in a mystic, reverential way and castigates humans for interfering in the natural balance of things and, sometimes, for having anything to do with animals at all. The other goes to the opposite extreme and talks mostly about sq cm of cage size and the regular collection of faeces. There seems to be little in between: it is as if one has either to be poetical in one's attitude to animals or adopt the earthiest sort of banality about the size of their cages or the cleanliness of their drinking water.

The sinking feeling occurred when I first looked at Laboratory Animal Husbandry by Michael W. Fox. However, despite its title, the book certainly does not fall into either of the usual categories. On the contrary, it is innovative in several important ways.

First, it documents recent evidence about the effects that totally unexpected factors may have on animal health and well-being. It is perhaps not surprising that noise, ventilation and ambient temperature can have significant effects on the health of animals and their susceptibility to disease. But it is probably less well known that the exact age of weaning and the amount of handling from a human being can affect, among other things, plasma cortiscosterone, prolactin and growth hormone levels. The behavioural and physiological changes that have been found can in turn affect not only the animals' own well-being but the results of experiments on, say, drugs. Some of these unexpected factors may radically alter the conclusions about how effective a treat-

A second, related point that Fox makes concerns an animal's social environment. It should be obvious, but it clearly is not to judge from current practice, that an animal's welfare cannot be safeguarded simply by concentrating on the bare necessities of food and water or even on the physical environment of its cage. Many animals are highly social. They interact, both positively and negatively, with other members of their species; it should not be BOOK REVIEWS

Improved conditions for animals could benefit humans too

surprising, therefore, that disturbances in their social lives can significantly affect their behaviour and health. Fox argues that our understanding of human ailments is far from complete and it is often impossible to pinpoint why one person becomes ill when another does not. If we are attempting to use animals as models of puzzling human diseases, he argues, we will continue to be ignorant unless we also begin to consider the complexity of the factors, including social ones, that affect the development of diseases in animals.

He concludes that there is a double imperative on us to imprové the welfare of laboratory animals. One is for the animals themselves: if we use them we should look after their welfare better than we do now by taking into account the range of factors, both physical and social, that can affect them. The other is for humans: if we want good scientific results, we should be more careful about the conditions in which we keep animals. There follows a useful chapter giving practical suggestions as to how laboratory animal husbandry could be improved for the benefit of both human and non-human animals. Another chapter contains a review of the main findings on pain and suffering in research animals.

One particularly appealing feature of the book is that the discussion of animal rights is kept to the last chapter. This means that even if you disagree with Fox on this issue or lose sympathy with the "land ethic" or "One Medicine", the rest of the book with its more down-to-earth reviews and suggestions, loses none of its value. The ethical issues are discussed but they do not intrude, so that the book can potentially appeal to, and be profitably read by, people with very divergent attitudes to animals.

The common thread is a concern for the welfare of animals in laboratories. Fox's contribution is to bring common-sense and research findings to bear on the problem of how we might improve it. He points to the arbitrariness of the present guidelines and laws as to how animals should be kept (the fact that recommended cage sizes for dogs, cats and primates in Britain are double those suggested by the American authorities, for instance). And his insistence that we should take more notice of the social needs and interactions of animals, and not just think in terms of their physical comfort, is a message that cannot be broadcast too loudly or too frequently.

Marian Stamp Dawkins is Fellow in Biological Sciences at Somerville College, Oxford OX2 6HD, UK. She is also author of Animal Suffering: the Science of Animal Welfare (Chapman & Hall, 1980).

Economical images

Peter Hawkes

Transform Coding of Images. By R.J. Clarke. Academic: 1985. Pp.432. Hbk. \$69.50, £60.50; Pbk. \$34.95, £31.

From the point of view of a computer, an image is a voluminous and cumbersome object. The human eye and brain can handle a continuous-tone picture effortlessly and almost instantaneously; for a computer, the image must be broken into small zones, each of which corresponds to a number representing the grey-level. There are typically 256 of the latter, and the number of image-elements or "pixels" can easily reach a million. For these values the computer already has 8 megabits to cope with, but if the image is coloured rather than black-and-white this must be multiplied by three. Worse still, although we may regard such an image as a 1024 × 1024 matrix, each element of which is an (eight-bit) number representing the greylevel of the corresponding pixel, in image processing we are also interested in statistical properties. If the image is represented by an N \times N matrix (N = 1024 in our example), then the matrix corresponding to such statistics will be $N^2 \times N^2$.

Everyday images contain much redundant information — uniform or slowly varying areas for example - and it is natural to ask whether a typical image could not be represented in the computer in a more economical way. This question has long preoccupied the image processing community and, although not quite so pressing with the advent of parallel and special-purpose computers, it will surely always be important for archival purposes. Various ways of coding images that occupy less memory space have been explored, and Roger Clarke's book is a detailed introductory account of one of these ways, notably the use of transforms, of which the Fourier is the best known.

The underlying idea is simple. Fourier transforms tell us what weight is associated in some signal with the corresponding frequency. We can therefore expect that if we suppress frequencies with very low weights, and reconstruct the signal from the remainder, the result will differ only slightly from the original. Converting this qualitative notion into quantitative terms is not so simple: how low must a weight be to be regarded as very low and hence negligible? How slight must the difference between original and reconstruction be to be acceptable? Is the Fourier transform a good choice and if not, which is the best transform to use? It is these and related questions that Clarke sets out to answer. He does so in eight chapters, plus an introduction, in which he examines image statistics, suitable orthogonal transforms, quantization, practical coding, the human visual response, fast transforms, errors and noise and, finally, rate distortion theory and coding. Seven appendices are concerned with specific mathematical points.

How successful he is depends on the sophistication of the reader. Everything is spelt out in detail: the laboriously gentle introduction of a matrix product at the beginning of the chapter on orthogonal transforms is a glaring example. Any physicist who has followed a course on quantum mechanics, not to say applied mathematics, will be exasperated by this, as will many electrical engineers, especially those with any familiarity with coding. Conversely, many readers will appreciate the detailed and careful definition of the many matrices that arise in image coding, and will be grateful for the frequent numerical examples that add flesh to the bare mathematical bones.

It must be said too that Clarke's is a leisurely style: "At the outset, it is worth clarifying one matter concerning the application of the theory...", he observes; and he likes telling us that "it is a truism nowadays to say" and that "it is no exaggeration to say that...". His discursiveness seems at odds with the aim of transform coding! Nevertheless, he has written a clear, readable and easy introduction to his subject, and those of us with images to code will often turn to his book to see what he has to say about some specific problem.

Peter Hawkes is Directeur de Recherche at the Laboratoire d'Optique Electronique du CNRS, BP 4347, F-31055, Toulouse Cedex, France.

Catalogue of inequities

John Maddox

The World of Science and the Rule of Law. By John Ziman, Paul Sieghart and John Humphrey. Oxford University Press: 1986. Pp. 343. £19.50, \$37.

This is not so much a book about the world of science and the rule of law as about what are called, in the United States, human rights — conflicts between personal liberty and the interests of the state. John Ziman, Paul Sieghart and J. H. Humphrey are, respectively, distinguished physicists, lawyers and biologists whose interests have repeatedly strayed beyond the narrow boundaries of their professions. Their failure, in this book, to do much more to describe a haunting problem is not their fault, but a measure of its difficulty.

The book has its origins in a pamphlet published more than ten years ago by the British organization called the Council for Science and Society, an unpaid and sometimes unprofessional Office of Technology Assessment. The starting point is the observation that the complaints of scientists that their professional freedom is too often administratively constrained is often at odds with the way in which most formal constitutions formally guarantee the freedom of the individual to do what he pleases.

Given the signature of the agreements on European security at Helsinki in 1979, the book cannot but in part be an account of the lamentable record of what has happened since. But little has changed. People who work in states where freedom of communication is guaranteed by the laws still discover that their letters are opened, sometimes to be confiscated, and their telephones disconnected. People whose governments are supposedly bound by the rule that employment should be open to all still find themselves denied the chance to work at what they do best when they give offence; the case of the Jewish refusniks in the Soviet Union is familiar, and necessarily a large part of the litany of oppression making up this book. Indeed, the Eastern bloc gets a real drubbing.

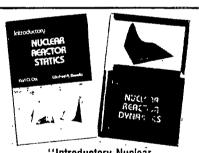

The authors might have made more of the way in which many western European States have been compelled by the European Convention on Human Rights to do the decent thing, against their first inclinations. Maybe there is more freedom now than, say, in the eighteenth century, even though the continuing deficiency of what is on offer remains just as offensive now as then. So the authors are right to ask why performance should so often fall short of promise. Why? A discussion of this point

would have been rewarding.

The truth is that the human failing of believing well and behaving badly applies to governments as well. Let us hope they may improve. How might the professional community urge them on? After what is a moving catalogue of unjustice, the authors have next to nothing to offer by way of remedy. They approve of the way that two successive presidents of the Royal Society have "spoken out", but have surprisingly little to say about the need for the outspoken to contain their protests within the other fellow's law. UNESCO's statements on the status of scientific workers are approvingly reprinted as an appendix, but the authors seem to share the general conviction that the source of all the words has no act to perform: ICSU is a better bet. Weisskopf's dilemma, that an illiberal society ostracized into exclusion can only become even more illiberal, is described but not resolved. And nowhere in this flat peroration is there a clear explanation, for the benefit perhaps of the young and cynical. of why it is that, if the law has a built-in momentum sweeping illiberality out of the way, then surely science must work the same magic but more powerfully. But is that not the only way in which it will come

Fifty years on

Warwick Bray

American Archaeology Past and Future: A Celebration of the Society for American Archaeology 1935-1985. Edited by David J. Meltzer, Don D. Fowler and Jeremy A. Sabloff. Smithsonian Institution Press: 1986. Pp.479. Hbk \$35, £35; pbk \$19.95, £19.75.

On 28 December 1934 the Society for American Archaeology came into existence. The following year the initial volume of American Antiquity appeared and the first annual meeting of the SAA was held (with 8 papers and 75 participants). American Antiquity has since become the leading journal in its field, and many people would argue that the SAA meeting is the major conference of the archaeological year. The present volume is a celebration of the society's 50th birthday — an appropriate age for looking back to the past, taking stock of the present and trying to set the younger generation on the right path for the future.

The 17 contributions are by North American practitioners belonging to the older and middle generations, but representing a range of differing archaeological theologies. They are neither complacent nor self-congratulatory. Cumulatively, the book adds up to a lively, and conspicuously well written, critique of the strengths and weaknesses of archaeology in North America. By sheer weight of numbers, the Americans have played a dominant role in changing the theoretical basis of archaeology (in the non-Communist world, at least), so this study is of more than parochial importance.

The editors divide the volume into three sections. The first looks backwards: it includes a personal reminiscence by Jesse Jennings, and historical surveys of the development of field techniques, the rise of the conservation ethic and the changing employment of the concept of culture. Bruce Trigger examines archaeology as a social phenomenon which reflects the changing interests and prejudices of the society that sponsors and pays for it (as an example, he notes how today's explanatory models reflect "current anxieties in middle-class American society about unchecked population growth, environmental destruction and the depletion of nonrenewable resources"). In similar vein. Don Fowler observes that the roots of the majority of Americans do not lie in the Indian past and, in consequence, there is no strong impulse to identify with and conserve that past. Each generation, it seems, gets the archaeology it deserves.

The middle section of the book consists of state-of-the-art surveys of three major problems: the nature of hunter-gatherer

societies, the origins of food production, and the evolution of civilized states and empires. These papers, though good of their kind, do not treat the issues historically and therefore seriously interrupt the continuity of the book. The main theme returns in the final section on current trends and future prospects (the role of mathematics and formal methods, problems of cultural resource management, how to reconstruct the symbolic and cognitive values of extinct communities, and an evaluation of our long-term intellectual options).

Sections One and Three should be compulsory reading for any one, not only Americanists, interested in the historical development and present health of the discipline. As the editors point out, in 1935 American archaeology was remarkably uniform, with generally agreed goals (historical reconstruction, above all) and universally accepted research methods. That is not true today, and one of the book's many virtues is that the polemics of recent years are not merely described, but also evaluated from a longterm historical perspective. One of the faults of recent Messiahs and their followers is a reluctance to read anything more than 10 years old, and it is good to see Donald Grayson demonstrating that "middle range research" — though not under that jargon title — goes back to the days of the controversy over eoliths, and to read Jennings's casual comment that he had "discovered, studied and discarded" (my italics) the philosophers of science long before Hempel was so uncritically taken up by the New Archaeology. Some scholars, including some of the most innovative, are traditionalists by considered conviction, not through ignorance or lack of imagination.

Without naming names or reopening old wounds, one can recognize from the data in this volume a fairly standard cycle of events. A new movement emerges (generally based on ideas developed in another discipline, and often just as these are beginning to go out of fashion on their home ground), is accepted uncritically by its devotees, fails to deliver the promised goods, gradually loses its adherents and is in turn replaced by another "new wave". The historical view presented in this volume demonstrates that, in the long run, the good (and there is always some) is retained and adopted into the mainstream of archaeology, and the sillinesses - like puberty spots — fade away with maturity. If archaeology is not to stagnate, this kind of intellectual ferment is vital to the wellbeing of the subject. Like most of the contributors, I look forward to the future with a guarded optimism.

Warwick Bray is Reader in Latin American Archaeology at the Institute of Archaeology, University of London, 31-34 Gordon Square, London WCIHOPY, UK.

Breeders' rights and patenting life forms

from Jean-Pierre Berland and Richard Lewontin

Academic freedom and scientific advance could be the casualties if the patenting of microorganisms becomes the norm.

WITH the advent of genetic engineering, I biologists have suddenly become acutely conscious that plants and animals can be factors in the production of consumer goods: like machines, they are commodities, sold for profit to manufacturers. This development has raised a host of issues about property rights in living organisms, the patenting of life forms and other questions that arise when commodities are produced for profit.

The excitement over genetic engineering may, however, obscure the fact that plants and animals have been factors of production of consumer goods for a very long time. The production of seeds and of animal breeding stocks for sale to farmers by seed companies and breeders have long ago raised the legal and economic issues of life forms as private property, used by manufacturing firms to appropriate profit. Moreover, research devoted to the production of new varieties or to methods of plant and animal breeding has always been, at least in part, influenced by the drive to increase the profits of breeders and seed companies. An analysis of the economic forces in the seed industry, as they have operated in the past and at present, may provide us with a framework for understanding future questions raised by newer biotechnologies.

Seed business

Seeds are a special kind of factor of production because, at least potentially, they are reproduced in the production process itself. Thus, in principle, a farmer could produce his own seed by withdrawing a small portion of his crop from the market. The problem for the seed company is to convince the farmer not to do this, but to buy this factor of production each year, just as he does fertilizer and herbicide.

There are two pathways open to the seed producer. The first is to achieve economies of scale, that is, to produce seed of the appropriate quality cheaper than can the farmer himself. As we will show, the profits from economies of scale are, in general, quite small. The second is to reap monopoly profits by creating seeds that are consumed in the production process; by providing objects that are not really seed in the biological sense that they are self-reproducing.

This is the secret of the hybrid method of breeding, which makes it impossible for

the farmer to hold back some of his crop as seed for the next year and which forces him to return each time to the seed company. Such monopoly profits can be very high. The search for them has had a strong influence on the direction of breeding research and on the drafting of laws and regulations governing seed production and sales in North America and Europe for 60 years.

It is our purpose here to provide a sketch of the economic analysis of the seed industry and to show how the attempt to maximize profits in the seed industry has influenced breeding and its organization. We will then discuss briefly the consequences of breeders' rights and the essential contradiction involved in patenting life forms.

Property rights

Any bag of seeds has two characteristics that must be distinguished carefully. The first set of characteristics, that the seeds should be weed-free, sized to fit mechanical planters, free from seed transmitted diseases, that they should germinate consistently to reach the proper plant density and that they should be available when needed in convenient forms at a reasonable price, are all traits that are a function of the technical process of seed production and marketing; they contribute to the profits of the seed producer under the heading of economies of scale. The second set pertains to the variety itself, its adaptation to the environment, its earliness, disease resistance, stress tolerance, yield, taste, processing qualities, nutritive value and so on. These characteristics are the result of the breeder's work, whether public or private. They are embodied in the genetic framework of the variety, are of a strategic nature and have an immense value. Marquis wheat, for instance, because of its earliness and disease resistance, made it possible to expand vastly the wheat-belt in the northern United States and Canada.

Yet, breeders find themselves in dire difficulties, for they have no property rights in the result of their labour. Farmers, no matter how much they benefit from the breeder's work, will pay only for the services of the seed producer, but not willingly for the work of the breeder. This is why breeding has had to be publicly financed until varieties - the result of breeding research and the invention that | pean system of protection:- the *catalogue*,

stems from it - become saleable commodities.

Historically, this has been done in two different ways. In Europe, governments have undertaken regulatory activities for a very long time and, more recently, this long-standing administrative protection has been reinforced by a legal system of plant breeders' rights. In the United States since the mid-1930s, the same goals have been achieved in the production of F hybrids, as is the case with corn. We will describe the historical origins of the system of breeders' rights and analyse its anticipated consequences before we turn to the biological solution sought by US plant breeders in the 1910s and 1920s

Breeders' rights

Breeders' rights have existed in Europe for more than 50 years, thanks to seed trade regulations, although the final convention forming the Union pour la Pro ection des Obtentions Végétales (UPOV) was not signed until 1961 and not ratified by national legislation until 1970 To understand how these rights were finally developed, we have to go back to the beginning of the twentieth century.

The first attempt to create a system of protection was to extend the patent system to new varieties, but patent lawyers rejected this solution on the ground that one of the basic requirements of patent law cannot be satisfied with biological material. Specifically, even full disclosure of the breeding work would not make it possible for anyone to reproduce the variety. Accordingly in France, breeders had to find more imaginative solutions, which resulted in a series of decrees, beginning in 1922, requiring that (1) seeds be sold under their proper variety name, labelled by variety and producer; (2) the breeder of the variety becomes the owner of the variety name, which is registered; and (3) only seeds of registered varieties can be offered for sale. Therefore, the breeder owns the variety.

In 1928, an "identity and purity" service was set up within the French ministry of agriculture to check the identity of the genetic material offered for sale and to control the purity of the seeds, thus establishing a de facto protection of breeders'

These are the two pillars of the Euro-

originally called the register, and (borrowed from the Dutch) certification, to protect farmers from poor plants. Fields are inspected, tests are run and plants are sold with a certification tag attached to the bag. If the tags are numbered and mention the name of the variety and of the producer of the plant, and if the records are kept, the breeder knows exactly the quantities of his variety sold.

When the catalogue and certification coexist, breeders are protected and de facto property rights to plant varieties are created without the intervention of legislation (see ref. 1). Only in the 1970s did European countries adopt legislation on plant breeders' rights giving this regulatory procedure a legal basis. But no such system can provide a mechanism to set the price of a breeder's work, nor is there a market mechanism that can establish one. This problem had to be solved by a regulatory mechanism to decide what the breeder's royalty should be.

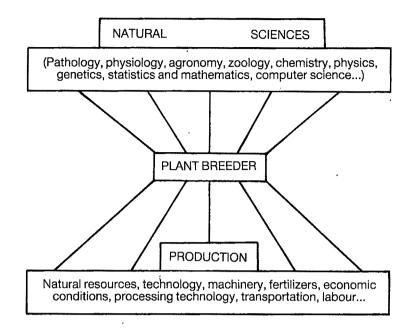

For clarity, we shall assume that the two functions of breeding on the one hand and of commercial seed production on the other are separate. We might suppose that, under the regulatory system of protection (or a breeders' rights system), the breeder can collect his royalties. The seed company can then add the royalty to its costs to set the price of the commercial seed, so that the cost of the breeding work would be paid for by the farmer.

This is not the case, however. Why would a rational farmer pay a second time for something he has already bought and still possesses in the form of his seed crop? The harvested grain has to be processed into seed; the farmer has the choice of doing it himself or buying the seed from a commercial seed company. Whether he chooses one or the other hinges on the importance of the economies of scale in seed processing.

Cleaning and sorting the harvested grain to get rid of foreign matter and of weed seeds, coating the seed with fungicides and insecticides and storing and keeping it in good condition until the next growing seson, after checking that it germinates, are simple and cheap operations; in France, they represent about 30 per cent of the value of the harvested seed. The sorting and cleaning equipment is cheap, easy to operate and readily available from country elevator operators at off-season times and prices. If necessary, machinery can be purchased and used cooperatively.

All this means that the profitability of the seed companies is low. Requiring them to pay for the breeding work is, for many, the last straw. In Britain, for example, a number of small seed companies went under after the breeders' rights law was passed. In France, where commercial seed is generally produced by cooperatives on behalf of their members, this

The strategic position of plant breeding

operation is often in the red.

To further illustrate this point, in 1985 the French government made it illegal for seed companies to process farmers' grain into seed. Why had seed companies apparently been undermining their own market? Because they were thus able to keep for themselves the benefit of economies of scale when processing farmers' seed, whereas they had to pay the breeder his royalty for every bushel of commercial seed they sold. Breeders and breeding companies sought to close this loophole and succeeded.

In the United States, the law allows farmers to use the harvested crop to provide seed for the next generation and even to sell it (although advertising is forbidden). This law is ambiguous on the question whether farmers may collectively use equipment to process their grain into seed, or have it processed for a fee, or trade the seeds of various varieties within a clearing house to avoid having to grow, harvest and process small quantities of each cultivar. It is likely that strong pressure will be exerted in the future by breeders and private seed companies to prohibit such operations, as the example of France demonstrates.

From this analysis, it can be seen that it does not make sense for a business enterprise to seek to integrate breeding and seed production: one loses what the other gains. (There is a striking difference with hybrids.) But breeding is a strategic activity that benefits the entire society. Should the cost be met by taxpayers or by a small group of enterprises, the small seed companies? And if the second, what steps can be taken to ensure that seed producers' profits will be sufficient to sustain such a

crucial activity? Especially now that breeding autogamous plants is less and less of a craft, and has become a specialized and capital-intensive operation, assurance is not easily arrived at.

As well as the hybrids, there is another significant exception to the qualitative conclusion of this analysis — the case of the occasional crops, such as soya beans, where the economies of scale in seed preparations can be very great. Because of the supposed fragility of the soya bean seed, it is said to be difficult for farmers to reproduce their own seed from the harvested crop. The question why mechanization research at agricultural experimental stations has not devoted more attention to harvesting techniques that would be less damaging to soya bean germ apart, soya bean is idiosyncratically closer to the category of monopoly profit seed production (see below) than to that of the small-grain cereals.

Changing rules

When no breeders' rights are in force, a public breeder will replace a variety only if he has developed a clearly better material. If a variety is widely used for years on end, so much the better. His fame, and that of his experiment station will be increased, and the farming community will lobby for increased appropriations when it becomes necessary.

For a private breeder, the problem is quite different. He has first to make his company profitable, which requires that there should be a commodity for sale. The strongest sales pitch is to offer "new" varieties. In other words, a private breeder has a vested interest in reducing as far as possible the lifetime of his varieties, to-

wards the ideal that farmers should adopt new varieties every year.

It is not therefore surprising that the statistics presented to the US Congress in 1980 have been described as "impressive". The same source says that ". . . three to six times more varieties of wheat, soybeans, and cotton were produced in the decade after the passage of the 1970 Act than in the preceding decade . . . This is probably a case in which the patent system actually achieves the intended goal of increasing research investment.

No seed company will advertise a nonproprietary item. Product differentiation through the creation and sale of proprietary varieties is essential if it is to remain competitive. The increase in the number of varieties offered for sale after the Breeder's Rights Act was passed in the United States is, for these reasons, not an adequate measure of the breeding effort aimed at increasing the agronomic value of the genetic material because, meanwhile, the objective of the breeders has shifted from that of increasing farm productivity to that of giving sales arguments to the marketing departments of the seed

Most breeders recognize that varieties offered by private companies are very similar. The argument that the number of varieties offered for sale has been multiplied, implicitly suggesting that it could be an index of the actual breeding work, is tantamount to measuring a temperature first with a Celsius thermometer, then with a Farhrenheit thermometer, and concluding that the temperature has approximately doubled. What the figures show is that breeders' rights increase oligopolistic non-price competition, but they leave unsettled how, and what sort of agronomic progress flows from the new rules of the game and whether it is more or less efficient than the alternative of publicly funded breeding work.

We would add at this stage that to contrast "market" and "public" breeding work is simplistic and inappropriate. The expensive, risky, time-consuming and unattributable task of developing new breeding techniques is carried out by the "public sector" with the intention that they should become the general property of all seed companies. At this point, private breeders step in to add small touches that can be made proprietary at small expense.

The structure that replaces a totally public breeding system is thus one of division of labour between public research, which does the non-proprietary work, and private breeders, who endeavour to use the work of public breeders in their own breeding programmes and proprietary commercial varieties. Far from disappearing into oblivion, public research will remain active, but will have to give up the production of commercial varieties. The

process of adjustment may be long and arduous, especially for the older public breeders who may cling to their ideal of serving the farmer, whereas they have now first to serve the seed industry, hoping that the "invisible hand" will accomplish what they used to do consciously. The United States and France, where it is a quasi-official policy that public research should keep out of commercial varieties, clearly illustrate the division of tasks created by a breeders' rights system.

Biological implications

It took four years for a committee of experts to elaborate the statute of UPOV (the Union for the Protection of Plant Invention). One of the stumbling blocks was the definition of the object of the convention⁴:

The word variety . . . applies to any cultivar, clone, line, strain hybrid susceptible to be grown and satisfying the dispositions of paragraphs (c) and (d) of Article 6. These paragraphs state that a new variety must be sufficiently homogenous and stable.

In fact, as UPOV itself recognizes, a variety is almost impossible to define⁵ "... the word 'variety' which is currently used does not have a commonly accepted precise definition". Since the very object of the convention is without a biological definition, we will not use the word "variety", which refers to a common sense notion and may confuse the issue, but instead use a meaningless term, varitrick, which is legally defined.

A new varitrick must be distinct from others. It has to be homogenous — the plants belonging to the same varitrick must look alike - and it has to be stable a varitrick should remain identical or almost identical over time. While these are the minimum criteria of patentability, they are also nothing other than a description of the steps of the method of breeding widely used for self-pollinated plants or to produce inbreds. Breeders artifically cross homozygous plants which display desirable qualities and then breed a series of generations, sorting out the plants which display the qualities of both parents, until they get a homozygous plant which, by definition, is a new (distinct) homogenous and stable varitrick. We thus have the principles of distinctiveness, homogeneity and stability (D-H-S) which are the basic principles for protection of breeders' rights all over the world.

In essence reliance on D-H-S as a criterion for a varitrick to be the property of a breeder outlaws other methods of breeding. The biological object, the variety, with its immense potential of variation, adaptation and evolution, is reduced to a varitrick, a much narrower legal object. For the sake of establishing property rights, plant breeders' imagination has to time, energy, and money have to be expended in fixing small anatomical differences (sometimes sensitive to the environment) in order to comply with the legal definition.

Let us again stress the self-contradiction of the system: if a varitrick is stable, the harvested grain is genetically identical with the seed and there is no need for an integrated seed industry. Breeders cannot make a living out of their work if they do not squeeze it out of the seed producer. If the variety is unstable and if the breeder/ seed producer knows how to control this instability and to maintain the basic agronomic characteristics of his variety (by F. hybrids, for example), only then will the farmer be ready to pay dearly for the breeders' services and be compelled to pay for the expenses of research and development.

Hybrids and monopoly

Barton, in his review of breeders' rights raises the science-fiction possibility that "DNA engineering will be applied to make the second generation of a seed artificially sterile . . ." and concludes that such an 'innate patent system' could pose enormous social costs in a concentrated industry. This forecast is to the point but at least 60 years behind the times. The F, generation of hybrid maize, if not biologically sterile, is economically unusable as seed, producing anywhere from 20 per cent to 40 per cent less than the F hybrid. For all practical purposes, such a loss of yield amounts to biological sterility.

In good maize areas, the use of F, seeds instead of commercial hybrids will cause a loss of 45 bushels per acre if a potential yield is 150 bushels per acre. The maximum price per bushel that an economically rational farmer will be willing to pay for his hybrid seed corn is theoretically equal to the loss per acre (45 times the price of maize per bushel) multiplied by the area sown with a bushel of seed corn (about 4 acres), which is the equivalent of 180 bushels of maize.

Even at present low grain prices, a bushel of hybrid seed corn is thus a potential gold mine, although seed companies do not, in fact, realize the maximum price. With grain selling at about \$3.00 per bushel, the maximum price of hybrid seed would be approximately \$450 per bushel, while the price, if the farmer could produce his own non-hybrid seed, would be a little over \$3.00. The actual price charged by seed companies for hybrid seed is about \$70 per bushel.

In the case of F, hybrids, monopoly profits are possible because the farmer is no longer the principal competitor of his supplier, and the regular game of interenterprise competition is re-established. Market structure then determines the profitability of the seed industry. If entry into be channelled into this narrow definition: I the market is easy and barriers to entry low, competition and particularly price competition will be intense, with the result that margins and profits will be low. On the other hand, if a seed company achieves a monopolistic position, it will charge much more. Research and development play the same role as expenditure on sales promotion and, under modern economic conditions, are in reality key elements in the strategy by which enterprises build barriers to entry through this sales effort.

Not only do the marketing staff and sales personnel need new products or varieties to launch their sales campaigns, but the creation of new varieties depends on the past investment in research and development. A breeding program may take anything up to 10 years to yield a commercial variety. Seed maize companies devote 3 to 5 per cent of their total income to breeding activities. This may not seem a very impressive figure when compared to sales expenses (20 per cent or more of total income) but for any newcomer, it is a formidable obstacle: one would have to invest money for years, perhaps in vain, before getting any return on one's investment. Since the time horizon of entrepreneurs is short, oligopolistic market structures are very stable over

Because hybrids expand the physical market for seed to the total acreage sown and because they make it possible entirely to disconnect seed prices from actual costs of production, they open up enormous opportunities for profit for private enterprise. In the last 15 years, most of the vegetable crops have become hybrid, but the great breakthrough that private (and, in many cases, public breeders as well) are pursuing is the production of hybrid seed for wheat, barley and soya beans.

Insofar as the breeders' hope is to repeat the success achieved with maize, however, they are likely to be disappointed. Success, of course, means profits. The claims that hybrid maize increased yields by a large proportion are totally unsubstantiated. Moreover, it can be shown that the margin of the seed industry in the sale of a variety of seed depends on the multiplication rate (the ratio of the quantity harvested to the quantity sown) of the variety⁷. The higher the rate, the higher the potential profits. But wheat, barley and soya beans have multiplication rates which are one tenth or less of that of maize. This explains why the only other grain crops so far to have gone hybrid are sorghum, millet and sunflower, the multiplication rates of which are at least equal to that of maize. The multiplication rate, the key to profits, has little to do with hybrid vigour, the biological phenomenon that allegedly justifies hybrid breeding schemes.

For wheat and barley, chemical inducing tillering is likely to increase the multiplication rate and therefore solve the seed companies' problem to some degree. If this is the case, the circle will be closed; the world seed industry has, in the past decade, passed into the control of powerful petrochemical and pharmaceutical corporations.

Conclusions

What we have described can be conveniently summarized in a set of concepts that provides a general framework for understanding some of the debates about biotechnology and property.

The specific factor of production implied in any biological process of production is genetic information. A wheat variety is a form of genetic information that makes it possible to make a better or more efficient use of the available resources, natural or technical. A strain of microorganisms used for the production of antibiotics is genetic information that makes it possible efficiently to use a substrate under precise conditions of pressure, temperature, acidity and so on.

Production in the economic sense involves a biological reproduction, which entails the production of genetic information in successive generations which can be identical, statistically similar or different to various degrees. For autogamous plants, barring mutations, the genetic information is identical. For a strain of microorganisms, mutations may occur during production, but the chance that they affect the useful part of the genome are negligible and, if they do, they can be selected against occasionally to keep their frequency low. For animals, the extent to which the useful genetic information is transmitted from parents to offspring depends upon the heritability of the character under consideration. In the case of openlypollinated varieties of plants, both the gene frequency and random disorder are preserved; for production purposes, the offspring are similar to their parents only on the average.

Thus, except for hybrid varieties, production implies a diffusion of genetic information which is available to anybody and which becomes a public good. Street corner sellers of tomatoes, beans and potatoes transfer, gratis, the genetic information built into the commodity sold. The case of microorganisms is different; the commodity sold is not the living thing but

its product once it has been killed. Between the fermenters and the pill or injection, there may be several complicated steps; the customer is not, in any case, a direct competitor of his supplier. Nevertheless, the genetic information circulates easily; the folklore of the pharmaceutical industry is full of stories of visitors carefully wiping their noses and sending back the tissues to their own laboratories. The essential point is that the good concerned, genetic information, is difficult to control exclusively and tends to circulate freely.

Those who have been promoting breeders' rights in Europe, in the United States and in the rest of the world, particulary in the developing countries, as well as those who seek to patent other forms of life, have not paid attention to the innate contradiction in what they do.

Limiting the use of a good available in limitless quantities at no cost will not be socially useful, will limit the full use of biological potential only to what is patentable, will erect barriers to entry in branches of production where competition is necessary and wil limit the free exchange of information between scientists so crucial to science. It would be unfortunate if the patenting system were surreptitiously extended to microorganisms. One may wonder what would have happened if the "Petition of Candle Merchants and Associated Industries against the Unfair Competition of the Sun", with its request that all openings of houses and buildings be covered, had been taken seriously. Frederic Bastiat's witty essay deriding the anti-free traders of his time applies exactly to the present situation.

Fractal growth processes

Leonard M. Sander

Physics Department, University of Michigan, Ann Arbor, Michigan 48109, USA

The methods of fractal geometry allow the classification of non-equilibrium growth processes according to their scaling properties. This classification and computer simulations give insight into a great variety of complex structures.

ALMOST every theoretical tool of the condensed-matter scientist uses the assumption that the system considered is of high symmetry and is in equilibrium. These assumptions have led to enormous progress; however, to much, if not most, of the natural world such tools cannot be applied. Many systems that we would like to understand are very far indeed from perfectly ordered symmetry and are not even in local equilibrium. Perhaps the most extreme example is disorderly irreversible growth. We mean by this the sort of process which is very familiar in the formation of dust, soot, colloids, cell colonies and many other examples; roughly speaking, things often stick together and do not become unstuck. For example, a particle of soot grows by adding bits of carbon and coagulating with other particles in a random way. A possible result is shown in Fig. 1. We are thinking about cases which are, in some sense, as far from equilibrium as possible, and which have no obvious order.

It is remarkable that the introduction of simplified models has led to quite a good understanding of the morphology of such growth, despite the inapplicability of our usual modes of thinking. Here I will discuss this progress, drawing examples mostly from subjects which have traditionally interested physicists and chemists. However, disorderly growth is ubiquitous in the world around us, and is certainly not limited to inanimate matter. For example, some of the ideas which I will discuss, such as anomalous scaling in kinetic processes, will be useful to biologists. The purpose of the review is to introduce ideas from the area which may be of general use.

The key to our recent progress is the recognition that the most 'interesting' non-equilibrium structures (say, from a visual point of view) are not merely amorphous blobs; they still have a symmetry, despite their random growth habit, albeit a different one than they might have had, had they grown near equilibrium. For example, consider the soot of Fig. 1, or the electrolytic deposit of zinc shown in Fig. 2. Many people will be familiar with branched deposits such as this, and with similar looking objects which form on automobile windshields on cold mornings. In all these cases the structure is disordered, but it is not random. A manifestation of this is that each section of the picture contains holes in the structure comparable in size with that of the section itself. This can only occur if there are longrange correlations in the pattern; particles 'know' about each other over distances far in excess of the range of the forces between them. A truly random pattern, such as that of salt scattered on a table top, shows no such scaling of holes, and correlations are of short range only.

Studies of fractal growth have focused on two questions: how can we characterize and quantify the hidden order in complex patterns of this type, and when and how do such correlations arise? The answer to the first question is now relatively clear, and lies in an application of the fractal geometry of Mandelbrot¹. The next section gives a brief review of relevant aspects of this subject. The second question has received a partial answer in the formulation and analysis of models suitable for computer

Fig. 1 Electron micrograph of soot. (Supplied by G. Smith, General Motors.)

simulation, which will also be reviewed. For more extensive treatments see refs 2-4.

Fractals and scale invariance

In pure mathematics, it has long been common to study certain 'pathological' geometric shapes that elude ordinary notions such as those of length and area. Figure 3 shows a famous example, which has, in some sense, infinite length, but zero area. It falls between our usual 'notions of line and solid. Mandelbrot¹ systematized and organized mathematical ideas concerning such objects due to Hausdorff, Besicovitch and others. But, more importantly, he pointed out that such patterns share a central property with complex natural objects such as trees, coastlines, patterns of stars and (as was later discovered) the non-equilibrium growths of Figs 1 and 2. This property is a symmetry which may be called scale invariance. These objects are invariant under a transformation which replaces a small part by a bigger part, that is, under a change in scale of the picture. Scale-invariant structures are called fractals.

There are a number of related properties which follow from the assumption of scale invariance. Consider, for example, the

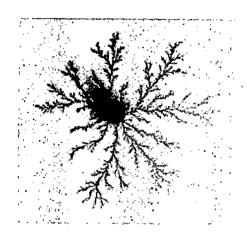

Fig. 2 Zinc electrodeposit produced in a thin cell under conditions of low ZnSO₄ concentration (0.01 mol l⁻¹). The outer electrode (not shown) is in the form of a ring 6.3 cm in radius. (Supplied by D. Grier, University of Michigan.)

density correlation function c(r), of a fractal. This is defined as the average density of the object at distance r from a point on the object, and is a measure of the average environment of a particle. Clearly, c(r) must reflect the scale invariance. It is easy to show that the only way that c may vary is as a power law in r; any other function would have an intrinsic scale. It is convenient to write c in the following form:

$$c(r) = kr^{-(d-D)} \tag{1}$$

Here, k is a constant, and the exponent is written in terms of the dimension of space, d, and a new quantity, D, the fractal dimension. The reason for this terminology will become evident in a moment. As the objects we are dealing with are tenuous, c(r) is a decreasing function of r: the average density decreases as the object becomes larger. Now consider how the total mass of the object, M, scales with the mean radius, R. We can estimate this by multiplying a typical density, from above, by the volume:

$$M(R) = KR^{D-d}R^d = KR^D \tag{2}$$

Here, K is another constant. We can now see why D is called a dimension. For an ordinary curve, D=1: twice the length gives twice the mass. For a disk, D=2. For simple objects D coincides with the usual notion of dimension. But in the cases we are discussing D is not an integer; it has been measured to be ~ 1.7 for the deposit in Fig. 2, and is 1.26 for the fractal of Fig. 3.

This anomalous scaling with radius, measured by D, is a very useful means of characterization because the fractal dimension is a 'robust' quantity. Like the famous scaling exponents of phase-transition physics, it has to do with long-range properties, indeed, with the relationship between properties at different scales. Thus we can expect it to be universal in the sense that it should be independent of the details of the interactions between the objects which stick together during the growth, of their detailed composition, and so forth. But, as we will see, the mechanism of growth does affect D.

Growth models

How might one visualize the growth of an object such as the electrolytic deposit in Fig. 2? As we are interested in long-range properties we can ignore the complications of electrochemistry and simply imagine that ions wander randomly in solution (in many cases the electric field is screened out so that this is a good approximation) and stick to the deposit when they happen to get near it.

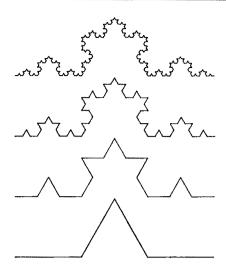

Fig. 3 Four stages in the growth of an exact fractal, the Koch curve. This and many other examples are discussed in ref. 1. The fractal dimension may be deduced by thinking of each picture as a part of the picture above, with a change of scale. For each scale change by three, we need four such parts. Thus, according to equation (2), $D = \log 4/\log 3 = 1.26$.

To make a computer model which is a literal translation of this process we start with a centre. Then we liberate a diffusing particle, a 'random walker', and let it wander freely until it is within a fixed distance of the centre, where it sticks. Then we liberate another particle and let it walk until it sticks to the centre or the first particle, and so on. We may, for our purposes here, idealize the process of formation as being completely irreversible: we ignore the possibility that the particles rearrange after sticking to find a more energetically favourable location. This is the diffusion-limited aggregation (DLA) model of Witten and Sander^{5,6}. The application of DLA to electrodeposition is due to Brady and Ball⁷ and Matsushita et al.⁸.

Figure 4 shows the result of an extensive simulation according to the DLA rules; its resemblance to Fig. 2 is evident. Measurements of DLA clusters have shown them to scale according to the relations quoted above, with D=1.7 for d=2, and D=2.4 for d=3. Note that the structure is tenuous and open because holes are formed and not filled up. Filling up the holes would require wandering down one of the channels in the cluster without getting stuck on the sides; a random walker cannot do this.

There are several features of the DLA model which should be mentioned. Although it is simple to describe, no progress has been made towards 'solving' it. That is, although we suspect, on the basis of simulations, that DLA clusters are fractals, we cannot prove it. And we have no method of calculating D (or any other property): we must measure it. There are several reasons for this (I will mention a rather technical one below), the primary one being that DLA presents us with a situation in which our experience in equilibrium systems doesn't seem to help. Note that D, along with other scaling properties, arises in a non-trivial way from the kinetics of growth: there is no simple geometric argument with which to predict them.

The DLA model can be generalized in various ways, for example, to describe deposition on a surface rather than a point. A more profound generalization is to use the model to describe systems which apparently have nothing to do with particle aggregation, but which share the same universal properties. We may see how one is led to do this by observing 5,10 that the probability, u, of finding a random walker at some point on its way to the aggregate has the following well-known properties: the flux of walkers; v, is proportional to the gradient of u, and, because walkers are absorbed only on the aggregate, this flux

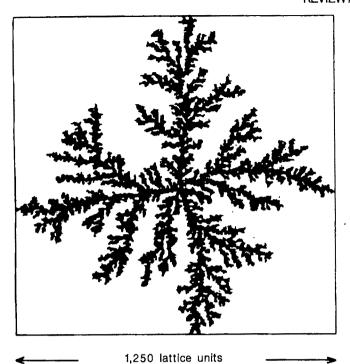

Fig. 4 A large DLA cluster (~50,000 particles) grown on a square lattice. Note the resemblance to Fig. 2, and the beginning of distortion towards a dendritic outline, as discussed in the text. (Supplied by P. Meakin, Dupont.)

has no divergence:

$$\mathbf{v} \propto \nabla u \tag{3}$$

$$\nabla \cdot \mathbf{v} = \nabla^2 u = 0 \tag{4}$$

As walkers are not allowed to escape from the aggregate, we set u = 0 on the surface. The growth of the aggregate is given by the flux at its surface, that is, by ∇u .

As Niemeyer et al.10 pointed out, a set of equations of identical form govern dielectric breakdown of a solid if we ignore many short-range details. As we are looking for universal features, making such simple, indeed, crude approximations is justified. If we think of u as the electrostatic potential in a solid about to be destroyed by a discharge, its negative gradient is, of course, the electric field. But u then obeys the Laplace equation of electrostatics, which is of the same form as the steady-state diffusion equation, equation (4), above. The breakdown channel will grow in a way determined by the electric field, that is, the gradient of u, on its surface. If the growth rate is linear in the field, we expect to have exactly the same situation as in DLA, and indeed, direct solutions of the equations, as well as measurements of photographs of real discharges, give the same fractal dimension as DLA. Non-linear breakdowns (lightning in the atmosphere is probably an example) give rise to patterns with different values of D.

Paterson¹¹ noticed an even more remarkable manifestation of the wide applicability of the model. When a fluid flows under conditions of large friction, inertial effects are negligible and the flow rate can be taken to be proportional to the hydrostatic force, that is, to the gradient of the pressure: this is known as D'Arcy's law. The situation is commonly realized in the laboratory by letting fluid flow between thinly spaced plates, a so-called Hele-Shaw cell. In nature, the flow of crude oil through the porous rock in which it is found is an example of quite serious interest. Suppose we try to force such flow by blowing a bubble of air or another low-viscosity substance into the cell (or by pumping water into an oil field—a scheme known as enhanced recovery). It has long been known that the air will not uniformly displace the fluid; instead it will break up into a complex

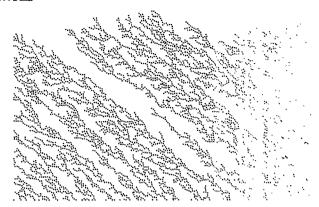

Fig. 5 Columnar microstructure in ballistic aggregation. Particles stick to the substrate and to each other after raining onto the structure in parallel trajectories at an angle to the vertical somewhat smaller than that of the columns. The fluctuations of the upper surface scale with the height for small height, and with the total width for large height. (Simulation performed by P. Ramanlal, University of Michigan.)

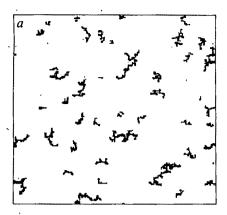

structure with many arms¹², which are called 'viscous fingers'. This phenomenon has an obvious detrimental effect on enhanced recovery.

Paterson's¹¹ speculation was that the pattern of the viscous fingering would scale like DLA. His reasoning was as above: the pressure in an incompressible fluid obeys equation (4), with u now standing for pressure, because fluid, like particles, is conserved. D'Arcy's law is of the same form as equation (3). Once more, many details have been ignored. In particular, the role of surface tension in this and similar situations will be discussed below.

The reasoning has been verified most directly by Chen and Wilkinson¹³, who introduced discrete randomness into a Hele-Shaw cell—the effect should be that of the random arrivals of Wilkinson¹³ particles. Their patterns look almost exactly like Figs 2 and 4. Another experiment, by Nittmann et al.14, used the clever trick of eliminating surface effects by taking for the two fluids water and an aqueous polymer solution; the fluids are miscible but mix slowly. Once more the pattern of fingering resembled the simulations. There seems to be a source of randomness in this experiment, probably arising from the non-newtonian flow characteristics of the polymer solution; such shear thinning could amplify noise. Even more startling is the experiment of Ben-Jacob et al. 15, who used a smooth Hele-Shaw cell, and one with a periodic pattern, with newtonian fluids. In some conditions they observed DLA-like scaling without an evident source of randomness, and without discrete 'particles'.

Experts will notice that equations (3) and (4) are of the same form (except for surface effects) as the description of solidification when the limiting factor in growth is diffusion of latent heat away from the surface of the growing crystallite. Why, then, does a snowflake (unlike the crystalline deposit of Fig. 2) not look like DLA, but is instead dominated by the crystal symmetry? I will return to this aspect of growth in the final section.

If particle aggregation doesn't need particles, what does it need? More generally, we can ask what different types of model give rise to scaling objects. For example, it is often the case that aggregates are formed by adding particles with a long mean free path, for example, in the formation of thin films by vapour-phase deposition¹⁶. In this case we may assume that the paths of the particles are straight lines. This model has become known as ballistic aggregation, and it has a number of very curious features. It is now known that the deposit itself is not a tenuous object but achieves a constant density^{17,18}. (In contrast, diffusion-limited growth on a surface⁹ yields an open deposit whose average density decreases with height.) It is of great interest to understand the upper surface of the film, which is a

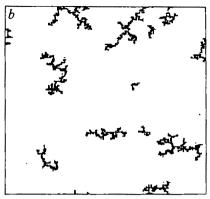

Fig. 6 Two stages in the formation of cluster-cluster aggregates: a, t=3,669; b, t=17,409. Note the resemblance of the clusters in b to the soot particle of Fig. 1. (Supplied by P. Meakin, Dupont.)

model of a random rough surface. It has been shown numerically¹⁹ that for normal incidence of the depositing particles this surface also has scaling properties: for example, the fluctuation of the height scales with a non-integral power of the height, for small height. This surface is probably not an ordinary fractal curve, like Fig. 2, but is probably an example of a self-affine fractal^{1,20}. 'Self-affine' means that the scaling in two different directions (width and height in this example) is different.

For non-normal incidence another effect appears, which is well-known in thin-film technology¹⁶. This is the columnar microstructure: the film spontaneously forms as a set of nearly parallel columns as it grows (see Fig. 5). The beginnings of a theory of this effect exist²¹, but it is not known what; if any, relationship these giant fluctuations have with the scaling fluctuations at normal incidence.

The simplest aggregation process of all was introduced into mathematical biology by Eden²². This is a model for the growth of a cell colony: a cluster is grown by adding particles at random to perimeter sites. Once again the object is compact, but the surface has interesting scaling properties which seem to be the same as for ballistic aggregates with normal incidence²³. Scaling is ubiquitous, and tends to have common features despite widely different details of growth.

We still have not described how soot forms. The structure of Fig. 1 is far more open than a DLA cluster: its fractal dimension is ~ 1.8 (DLA in three dimensions has D = 2.4). Extensive measurements of soot²⁴, colloids²⁵ and other similar objects leads one to suspect that a different class of clusters is involved. In fact, we have omitted a central feature of the formation process of clusters which can coagulate, namely the aggregation of clusters with each other^{26,27}. Figure 6 shows two stages of a simulation of this process in two dimensions. We start with a vapour of freely moving particles which stick together whenever they come into contact, and then allow the clusters to continue to move with, perhaps, a smaller diffusion constant. The large fractals which are eventually formed have D = 1.4. The corresponding simulations in three dimensions give D = 1.8 and yield the open structure of real colloids and aerosols. At each stage of the process almost all of the clusters are of roughly the same size.

The open structure and low fractal dimension which characterize cluster-cluster aggregation are relatively easy to understand. It is difficult for a random-walking particle to penetrate a significant fraction of the radius of a growing cluster for particle aggregation; it is even more difficult for an aggregate of comparable size to do so. Thus, as aggregation proceeds, open, fluffy structures are produced.

One variant of this model which is worth mentioning is reaction-limited (chemically limited) aggregation²⁸. In many cases, because of the details of the growth process, the sticking is inefficient, and many attempts are required to form a new cluster. In the limit of a very large number of attempts, the fractal dimension increases from 1.8 to ~2. Reaction-limited aggregation was probably discovered experimentally²⁹, before the simulations were done. Later experiments³⁰ have carefully

controlled the growth conditions and shown both growth mechanisms, and both types of geometry, in the same system for different growth rates. The encoding of kinetics in the scaling in a form independent of details should be a powerful tool for identifying growth mechanisms.

Attempts at theory

There is no general theory of irreversible growth. The descriptions given in the previous section must be regarded as a kind of phenomenology, albeit a useful one. We can point to situations in which there is scaling, but we are compelled to do experiments, either in the laboratory or on the computer to calculate anything. We do have a few analytical results, but they give only partial information.

The best understood type of aggregation is the cluster-cluster process. Suppose we assume, as stated above, that the dominant cluster-cluster collision is between clusters of similar mass. If we make the masses strictly equal we have a hierarchical model³¹. It is easy to believe then that we do have a fractal: agglomerating parts in this way is exactly how the artificial fractal of Fig. 2 was made. (Note that particle aggregation is not hierarchical, but it seems to be fractal nonetheless.) The specification of the size distribution of clusters in the vapour, and the verification of the hierarchical assumption, have been the objects of detailed studies³² which have shown that, indeed, the most common collision is between clusters of nearly equal mass. Some of these investigations use the techniques of colloid chemistry, in particular the Schmoluchowski kinetic equations, as well as computer simulations.

There remains the problem of finding the geometry of the clusters formed. Some progress has been made here because of a detail which allows one of the favourite tricks of the theoretical physicist to be applied. The real difficulty in visualizing the process is excluded volume, that is, the tendency of clusters to get in each other's way because they can attach to each other only on the outside. If they could attach anywhere it would be much simpler to sort out what is going on. It is quite obvious that excluded volume problems become less serious in high spatial dimensions: there are more ways into a three-dimensional cluster than into a two-dimensional one. Often, in equilibrium studies, it is found that for sufficiently large dimension of space, d, excluded volume is no problem at all: essentially any part of a cluster is accessible from outside. The dimension at which this starts to happen is called the upper critical dimension.

Above the upper critical dimension, calculations are simple, anomalous scaling is independent of d, and there exist methods (for equilibrium problems) which allow us to extrapolate to the physical world of d=3. For cluster-cluster processes, this is exactly what happens³³. The fractal dimension, D, for a cluster-cluster aggregate cannot grow above ~ 3.4 and it attains this value at about d=7. This is rather far from the real world, of course, and no one has yet figured out how to extrapolate.

The situation for particle aggregation is very different. Suppose that the entire cluster were to become accessible to added particles for a large enough value of d. Then the mass in the

interior would grow without adding to the volume. The cluster would quickly become so dense that it would no longer be accessible. Thus, there is no upper critical dimension for DLA. In fact, careful considerations of this sort can be turned into a bound³³ on D:

$$d-1 \le D \le d \tag{5}$$

The fractal dimension is never independent of the spatial dimension, and the standard technique cannot be applied.

Some progress has been made in the study of particle aggregation by exploiting the similarity of the process to the famous 'snowflake' problem, that is, the study of dendritic crystallization³⁴. We can see, for example, why tenuous structures are likely to arise in DLA and not in ballistic aggregation by noting that in the DLA case we have a growth instability of exactly the same form as the well-known Mullins-Sekerka35 instability of crystal growth. The reasoning^{5,35} goes as follows: suppose we start with a smooth aggregate and ask why it grows sharp tips. If we start with a tiny bump on the surface it will be magnified into a tip by the fact that the bump will grow faster than the rest of the surface: it will catch random walkers more efficiently than the flat portions of the surface, and certainly much more efficiently than the holes in the aggregate. The analogous dielectric breakdown case will make this even clearer: recall that the growth rate of any point on the surface of the structure is proportional to the electric field there. Sharp tips have large electric fields (the lightning rod effect). They grow ever sharper and dominate the growth. In the viscous fingering problem the same instability arises because it is easy for viscous fluid to flow away from a growing tip. It is even possible to specify a relationship between D and the characteristic opening angle of the tips³⁶ by using the mathematical theory of lightning rods. Unfortunately, no one knows how to calculate these angles. In fact, recent work indicates that there is an array of sharp tips on the surface of the fractal DLA cluster whose distribution is itself fractal37

For ballistic aggregates or for the Eden model there is no growth instability: it is easy to see that a bump on the surface neither grows or shrinks, but just adds a uniform skin, and tips do not grow. The bulk of the material remains compact.

Fractals and snowflakes

In the last section we noted the usefulness of the analogy of DLA with the kind of solidification most familiar (at least to those in cold climates) in the formation of snowflakes, that is, branched (dendritic) crystals. But particle aggregates do not look like snowflakes. To be precise, in a typical dendrite, a growing tip forms by the Mullins-Sekerka instability but then stabilizes. It retains its shape and continues in a definite direction, although it may spawn side-branches as it grows. In DLA (and in, for example, the zinc deposit of Fig. 2) the tips repeatedly split and wander.

There are three obvious differences between DLA clusters and dendritic crystals: DLA has essentially zero surface tension, it has a significant source of noise in the discrete arrivals of the particles, and it has (at least in some versions of the model) no analogue of crystal anisotropy. Sorting out how these affect the process is a subject of current controversy and great intrinsic interest.

Surface effects can be added in various ways to DLA simulations^{5,38,39}; the result is to thicken the branches of the aggregate, but the scaling is unaffected for large sizes. Nor do surface effects, by themselves, make the equations of crystallization give rise to snowflakes^{40,41}. Instead, something unexpected happens: a growing tip with surface tension does not stabilize, but undergoes repeated splittings, which are caused by the surface tension itself. This is because surface tension slows the growth of sharply curved surfaces and the end of the tip is the most sharply curved. In order to make real dendrites, anisotropy arising from the crystal structure must be introduced. The relationship of anisotropy to tip-splitting was verified experimentally¹⁵ using fluid flow in a Hele-Shaw cell with a lattice of grooves.

How does this relate to DLA? It is common to do DLA simulations on a lattice (for convenience). Will the same thing happen here as in the noise-free case; that is, will stable tips form because of lattice anisotropy? It seems that the answer is yes^{42,43}: sufficiently large clusters on a lattice have the outline of a crystallite, with tip splitting only on a small scale. But why, without surface tension, do we ever get tip splitting? This is because noise due to the discreteness of the arriving particles can split the tips. This can be verified in various ways, for example, by experiments and calculations which vary the noise¹³ at fixed anisotropy. In cases where tip splitting is mainly due to surface tension rather than noise, will we get an object which scales? The answer to this question is not yet clear, but there are indications^{15,44} that there is scaling, and that it is close to that of DLA.

These considerations are of more than technical interest, because they show how small effects (such as anisotropy) can make qualitative changes in growth habit. A series of recent experiments^{45,46} have shown, for example, how changes in growth conditions, such as an increase in voltage in electrodeposition, can change a fractal pattern like Fig. 2 into an ordered dendritic crystal by increasing the effective anisotropy. This is a fascinating example of the competition between scaling symmetry and ordinary spatial symmetry.

This work was supported in part by NSF grant DMR 85-05474. I thank M. Sander and R. Merlin for comments on the manuscript, P. Meakin, G. Smith, D. Grier and P. Ramanlal for illustrations.

Note added in proof: There have been two interesting recent attempts 47,48 to explicate the competition between anisotropy and noise.

The Cretaceous/Tertiary boundary has been identified in the Gosau beds (Elendgraben) near Salzburg, Austria. The undisturbed 2-mm thick boundary clay in the palaeomagnetic G^- zone differs from the surrounding sediments in having significant colour, no biogenic calcite and different contents of rare-earth and siderophile elements, carbon and magnetic minerals. The clay also contains shocked quartz and plagioclase particles, and indicates a dramatic change in sedimentation caused by a short-lived event.

THE discovery of an iridium anomaly at the Cretaceous/Tertiary (K/T) boundary has prompted a worldwide search for complete boundary sections. In Austria, prospective areas were examined for undisturbed boundary layers marking the event at the end of the Cretaceous period. To date, among several sections visited, only the Elendgraben in the Gosau Basin has been found to contain a complete sequence of sediments 18.

We present here a brief but thorough study of the outstanding exposure at Gosau. The combination of geochemical, geomagnetic, mineralogical, palaeontological and sedimentological analyses provides a coherent and surprisingly precise picture of the events which took place at the K/T boundary. A more detailed presentation will appear elsewhere (A.P. et al., in preparation).

Methods

In the course of detailed mapping of the Upper Gosau formation, hundreds of spot samples were collected and their fossil contents (nannoflora and microfauna) examined; this allowed the position of the boundary to be accurately located. In addition, 187 oriented rock cores were drilled for magnetostratigraphic studies. All core samples were thermally cleaned at 300 °C (and some cores at 360 °C) for rock magnetic analyses. The carrier minerals of the remanence are magnetite and/or titanomagnetite, as well as haematite. The mineral composition

Grain-size analyses of the sediments were performed with a sedigraph; chemical element analyses were carried out by X-ray fluorescence. For trace element analyses, neutron activation was performed at the Atominstitut der Österreichischen Universitäten, Vienna.

Site description

In the Elendgraben, near Gosau, which is a steep creek on the western slope of the Hornspitz-Höhbühel ridge (13°28′20″ E; 47°33′23″ N), flyschoid sediments of the Zwieselalm strata are exposed at an altitude of 1235 m (Fig. 1). The outcrop contains a >30-m thick sequence of southeastward-dipping sediments (dip angle 40°; dip azimuth 140°). The flyschoid sediments consist of alternating sandstones, siltstones, limestones, marly limestones and marls, which are partly turbiditic and partly hemipelagic. The sequence of these sediments indicates sedimentation in a deep-sea environment above the calcium carbonate compensation depth (CCD)². As shown by palaeocurrent patterns, the transported material, mostly metamorphic grains, was moving from south-east to north-west³.

The remarkably well preserved K/T boundary layers lie in a 16.7-m section of the palaeomagnetic reversed G⁻ zone (chron 29-R), 12.0 m above the magnetic polarity zone F₃⁺ (top of chron

was determined by means of X-ray diffraction, microprobe analysis, optical methods and electron microscopy. The samples were decalcified by decomposition with dilute acetic acid (10%), and the carbon contents determined by microanalyses.

EVENTS

REDEPOSITION

67.0

F3+

30-N) and 4.7 m below the H⁺ (base of chron 29-N), as shown in Fig. 2. Figure 3 shows a comparison of the sediment thickness of the G-zone at Gosau (16.7 m) with those of other K/T boundary sites—such as Caravaca, Spain (16.8 m), DSDP site 524, South Atlantic (13.9 m), Stevns Klint, Denmark (8.8 m) and Gubbio, Italy (5.2 m)—which have approximately constant ratios of G⁻ (Tertiary) to G⁻ (Cretaceous)⁴⁻⁷. The overall thickness of the G zone depends on the type of sedimentation, specifically, the extent to which biogenic calcite is diluted by turbidites and/or continuously deposited terrigenous materials. The lowest sedimentation rates are found in pelagic deep-sea sediments, where the highest biogenic sedimentation rates are combined with the smallest amounts of terrigenous dilution (for example, the Gubbio G⁻ zone is only 5.2-m thick and contains 95% CaCO₃). The much greater thickness of the G⁻ zone at the Elendgraben section (Gosau) results from turbiditic and hemipelagic sedimentation. Discontinuously deposited turbidites account for ~48% of the thickness of these sediments (8.1 m); the remaining 8.6 m is taken up by hemipelagic limestone sediments containing 62% calcite (5.3 m biogenic calcite and 3.3 m terrigenic material); thus, the total amount of terrigenous material (bulk density $\approx 2.55 \text{ g cm}^{-3}$) deposited within the G zone is 8,400 kg m⁻²

The duration of the G⁻ zone is 470 kyr (ref. 8): this yields a mean sedimentation rate of 1.83 cm kyr⁻¹ for the continuously

deposited hemipelagic limestone at Elendgraben, compared with 1.1 cm kyr⁻¹ for limestone sedimentation at Gubbio.

Palaeomagnetic directions from the Elendgraben K/T boundary (declination = 191.4; inclination = -51.8) indicate a palaeolatitude of 32° N. Ness et al.9 assigned an age of 66.7 Myr to the K/T boundary; in palaeocontinental maps of that age, the Gosau Basin is shown lying within the Tethys, which at that time had open connections with an east-west circulation system 10,11 .

Biostratigraphy

Two major fossil groups showing characteristic changes at the K/T boundary were studied in detail: the calcareous nannofossils and the planktonic foraminifera (Fig. 2). In the former group, the uppermost Maastrichtian assemblage contains the marker fossil Micula murus. In the marly limestone below the K/T boundary layers (samples C-1 to C-30), the nannofossils are partly recrystallized and poorly preserved; however, in the 3 mm of grey marl (C-0.3) of the K/T boundary layers underlying the light-brown K/T boundary clay (CT), they are well preserved. The K/T boundary clay itself is practically devoid of nannofossils, although some chamber fillings of foraminifera of uncertain origin are found. The foraminiferal microfauna below the K/T boundary layers belongs to the Abathomphalus mayaroensis zone. In the few centimetres above the K/T boundary clay, some reworked Maastrichtian foraminifera were found. Reworking of nannofossils from Cretaceous to Tertiary is also demonstrated by the presence of both Maastrichtian and Campanian coccoliths, such as Aspidolithus parcus.

Two centimetres above the K/T boundary clay, there is a sharp increase (by a factor of at least 10) in the frequency of the spherical calcareous shells of the dinoflagellate Thoracosphaera operculata, which is rather rare in the Upper Maastrichtian and becomes the dominant nannoplankton species in the K/T boundary layers. Perhaps the cells of Thoracosphaera operculata had better survival chances in case of a strong reduction of photosynthesis than many other unicellular species and also

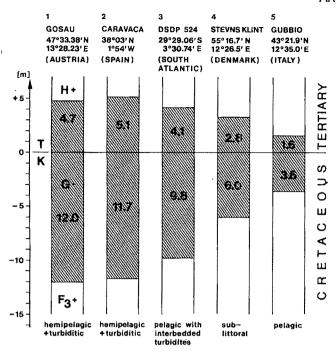

Fig. 3 Comparisons of the magnetic polarity zone G⁻ (chron 29-R) at different sites (Austria, Spain, South Atlantic, Denmark and Italy), with different types of marine deposits. The numbers above and below the K/T level indicate sediment thickness within that chron in Tertiary and Cretaceous, respectively.

had the ability to form close protective globular cysts. Biantholithus sparsus, the first Danian marker among the nannofossils (zone NP 1), is found immediately above the K/T boundary clay.

The first specimens of Globigerina fringa were discovered ~6 cm above the K/T boundary clay. In the Elendgraben outcrop, the lowest occurrences of the nannofossils Cruciplacolithus primus, C. tenuis (marking the base of the NP2 zone) and Globigerina eugubina lie very close to the change from the G⁻ to the H⁺ palaeomagnetic chron. There is strong agreement in biostratigraphical data between the Elendgraben section and equivalent sediments ~46 km away, in the Lattengebirge, Upper Bayaria¹².

Deep-sea sediments

The deep-sea sediments across the K/T boundary at the Elendgraben consist of marly limestone, K/T boundary layers and silty marl (Fig. 2), and do not contain turbidites.

The marly limestone (C-30 to C-1; thickness 30 cm) underlying the K/T boundary layers is consolidated and compact; it consists of 77% biogenic calcite (nannofossils and foraminifera), diluted by 23% non-biogenic components (quartz, feldspars consisting predominantly of oligoclase, mica, 14-Å-chlorite, smectite, illite and mixed-layer clays), the terrigenous sediments having the grain-size distribution: 3% sand, 30% silt and 67% clay. The Ir content is <0.5 p.p.b., the magnetic fraction is <0.02% and the organic carbon level is $\sim 0.1\%$.

The K/T boundary layers (C-0.3 to T3) comprise $\sim 4 \text{ cm}$ of unconsolidated and porous material. The boundary layers comprise (from base to top) 3 mm of grey marl (C-0.3), 2 mm of light-brown K/T boundary clay (CT), 3 mm of grey marl (T0.3) and another 30 mm of grey marl (T1 to T3). The mean composition of layers T1 to T3 is 20% biogenic calcite, diluted by 80% non-biogenic components (quartz, feldspars, mica, 14-Å-chlorite, smectite, illite, mixed-layer clays and kaolinite) with mean grain-size fractions: 8% sand, 54% silt and 38% clay.

The 2 mm of light-brown boundary clay (CT) has a very different chemistry and mineralogy from the rest of the sediments

(see below); notably, it contains no biogenic calcite, and displays characteristic changes in the contents of certain trace elements ('geomarkers'), which reveal an event in Earth history by a marked increase or decrease in their quantity. Because of the worldwide presence of a significant iridium peak, the middle level of this thin layer (CT) is defined as the level of the Cretaceous/Tertiary (K/T) boundary. All distances given here are referred to this level.

The silty marl (T4 to T17) above the K/T boundary layers is 13 cm thick and friable. The content of biogenic calcite lies between 20 and 27%. The non-biogenic components have nearly the same mineral composition as the Cretaceous marly limestone but coarser grain sizes.

The grain size distributions show a mean size of quartz grains of $\sim 8 \mu m$ for the Cretaceous marly limestone, and $\geq 20 \mu m$ for the Tertiary marls and silty marls.

Chemistry and mineralogy

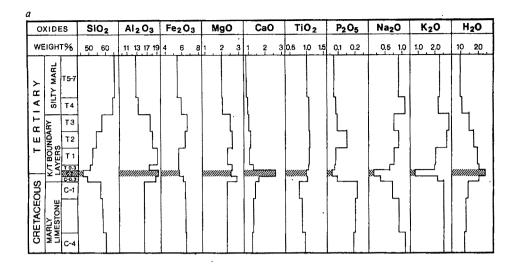

We have used a combination of X-ray fluorescence, X-ray diffraction and microprobe analysis to determine the chemical contents and mineral compositions and abundances in decalcified samples. Some trace elements were analysed by neutron activation. Figure 4 shows the results of the chemical analyses of oxides and trace elements in samples C-4, C-1, C-0.3, CT, T0.3, T1, T2, T3, T4 and T5-7 across the K/T boundary, as well as information regarding their contents of transported quartz, expandable clays, kaolinite, magnetic fraction, elemental and organic carbon.

The samples of the Cretaceous marly limestone (C-4 and C-1) and the Tertiary silty marl (T5-7) are of similar composition. In contrast to these, however, is the dramatically different composition of the K/T boundary layers (C-0.3 to T3), especially the boundary clay (CT) with its extraordinary chemical and mineral composition. The 2-mm boundary clay (CT) contains no biogenic calcite (Fig. 2); a minimum of quartz, plagioclase, mica and 14-Å-chlorite; a minimum of SiO₂, Na₂O and K₂O; relatively high amounts of kaolinite and expandable clays with high water content (Ca-smectite and mixed-layer clays); and peak values of magnetic minerals, such as exsolved ilmenite (FeTiO₃) in magnetite (Fe₃O₄), formerly titanomagnetite. The weight percentages of the authigenically formed minerals (kaolinite, Ca-smectite and mixed-layer clays) total ~94%, which, like the Ir content of 14.5 p.p.b. (parts per 10°), is a peak value. The high Ir content of the boundary clay (CT) was shown to be related to the titanium mineral and not to the magnetite. A marked increase of carbon, as determined by microanalyses, is also apparent in the K/T boundary layers.

The bulk of the 2-mm-thick boundary clay (CT) is comprised of fallout material (mainly glass and its derivates, and shocked and deformed minerals). The succeeding sequence of K/T boundary layers (T0.3 to T3) also contains reworked, transported and redeposited material, indicating different sedimentation processes.

The >20- μ m fractions of decalcified marl and clay (C -0.3 and CT) were examined for the presence of shocked particles (Fig. 5), using a polarizing microscope equipped with a universal stage, and also by means of X-ray diffraction and transmission electron microscopy (TEM). X-ray analysis shows that 70% of the fraction is quartz, the remainder consisting of feldspar and kaolinite. Whereas the quartz in the underlying Maastrichtian (C-1 and C-4) is a fine groundmass with <10% of 10- μ m clasts (undeformed to slightly deformed), the quartz of the samples C-0.3 and CT is clearly shocked. Shocked quartz was first reported at the K/T boundary in Montana¹³.

In the shocked quartz of the Elendgraben, shock features include lamellae indexed to $\{10\overline{1}3\}$, $\{10\overline{1}1\}$, $\{10\overline{1}2\}$, $\{0001\}$, $\{11\overline{2}2\}$ and $\{11\overline{2}1\}$, planar cleavages shown to be microfaults in laboratory shock specimens, symplectic material, and widespread vitrification¹⁴. Eighty-two of more than 100 grains in sample C-0.3 were identified as quartz, showing the following

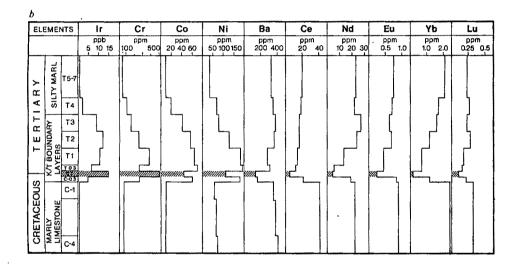

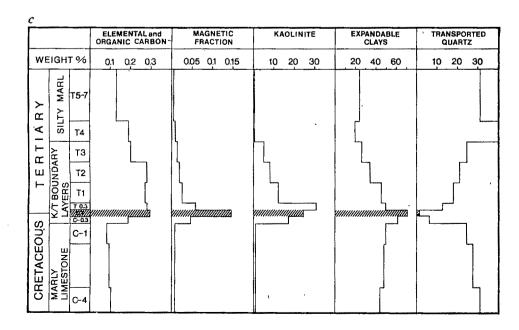

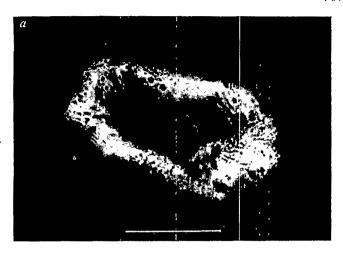

Fig. 4 Analyses of samples across the K/T boundary (Elendgraben), after decalcification. a, Distribution of major-element oxides; b, contents of trace elements (geomarkers); c, biogenic and non-biogenic material. Shaded area, K/T boundary clay (CT).

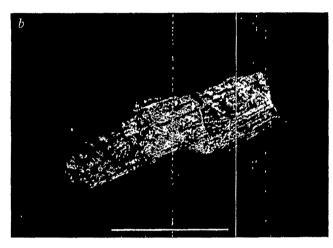

Fig. 5 Photomicrographs of minerals deformed by the K/T boundary event (Elendgraben). a, Shocked quartz grain (sample C-0.3) with lamellae; b, shocked plagioclase grain (sample C-0.3), with numerous planar features. Scale bars, $10 \mu m$.

features: 8 grains contain shock lamellae; 40 grains contain microfault sets: 26 grains contain isolated microfaults, decorated (partially annealed) microfaults, and/or planar edges; 3 grains are largely vitrified, symplectic, or melted; 3 grains show only internal fracturing; and 2 grains show no distinct signs of shock. All grains show mild to extreme undulatory extinction. These results are confirmed by TEM, which showed an enormous quantity of amorphous material; microcrystallites distributed in amorphous material; consistently planar grain edges, usually decorated with glass; planar glassy areas; and no or few dislocations. It appears that essentially all quartz grains examined are shocked and broken along shock microfaults. Furthermore, material too fine or too coarse for the survey shows a similar distribution of effects, so that the majority of 20-µm quartz—that is, approximately half of the 11% quartz from sample C-0.3—is shocked to varying degrees (Fig. 5a).

Feldspar grains show similar effects (Fig. 5b), including planar features and edges, undulatory extinction, and widespread glass in TEM. Phyllosilicates, however, have none of the distinctive shock kink bands. Material from the boundary clay (CT) is similarly shocked, but contains conglomerates of shocked grains, more rounded grains, and recrystallized material with relict microfaults and lamellae. This material was shocked and then annealed and deposited. Also, large, euhedral, twinned calcite crystals are found.

The presence of shocked particles in sediments, in connection with the mass extinction of foraminifera and nannoplankton is considered to be evidence for an extraordinary event. Furthermore, the enrichment of geomarkers such as Ir, Cr, Co and Ni, and the depletion of geomarkers such as Ba and the rare-earth elements (Fig. 4), indicate that the event marking the K/T boundary could be caused by an impact of an asteroid of nearly chondritic composition, as suggested previously^{15,16}. The mass of such an asteroid can be estimated from the total amount of excess Ir deposited in the K/T boundary layers. Such a calculation¹⁷ yields a diameter of >8 km, which is in agreement with data in ref. 1. The shocked quartz and plagioclase, the rock fragments, the Ca-smectite, the twinned calcite crystals, the excess of Mg and Ca ions in the K/T boundary layers, and the global distribution of a large amount of chondritic material indicate that the event was initiated in the ocean. The amount of the crater material that was ejected into the atmosphere after the impact and distributed across the globe can be calculated from the fallout and its derivatives (kaolinite, mixed-layer clays and Ca-smectite), plus the amounts of reworked and redeposited

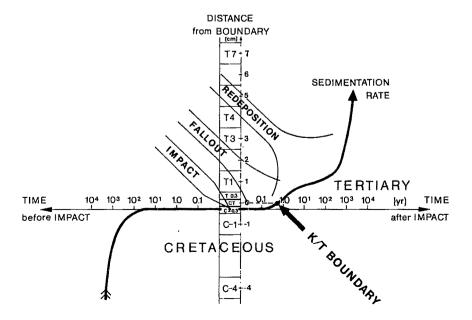

Fig. 6 Time structure of the event at the end of the Cretaceous period: sediment thickness (linear scale) is plotted against time before and after impact (logarithmic scale). Periods of impact, fallout and redeposition are indicated, as is the K/T boundary (defined by the Ir peak).

material¹⁷. This amount deposited as a compact sediment layer across the globe corresponds to a thickness of ~9 mm.

Conclusions

The distribution of the geomarkers and the mineral components (Figs 2, 4) in the K/T boundary layers (C-0.3 to T3) suggests that there was a short period of 'fallout', followed by a redeposition of the fallout material over a longer period of time. On the basis of the analyses given here, Eder and Preisinger¹⁷ have concluded that the time required for the deposition of the K/T boundary layers was much shorter than for any other layers in the sequence. As shown in Fig. 6, where sediment thickness is plotted on a linear and time on a logarithmic scale, the impact itself (t=0) occurred within layer C-0.3 and is not identical with the K/T boundary indicated within layer CT. This is consistent with the idea that the material ejected into the atmos-

phere returned to the Earth over a period of time, which would explain why the Ir peak is not synchronous with the impact.

The combination of the analytical results and the time-structure analysis of the K/T event suggest that, 66.7 Myr ago, an impact of an asteroid took place, producing a worldwide geochemical and mineralogical anomaly within a very short stretch of time and causing conditions for mass extinctions of large quantities of biota.

Tight linkage between a splicing mutation and a specific DNA haplotype in phenylketonuria

Anthony G. DiLella*, Joshua Marvit*, Alan S. Lidsky*, Flemming Güttler* & Savio L. C. Woo*

* Howard Hughes Medical Institute, Department of Cell Biology and Institute of Molecular Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, Texas 77030, USA † John F. Kennedy Institutiet, Gl. Landevej 7, DK-2600 Glostrup, Denmark

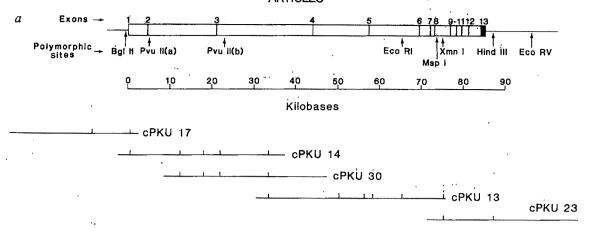

The first phenylketonuria mutation identified in the human phenylalanine hydroxylase gene is a single base substitution (GT→AT) in the canonical 5'-splice donor site of intron 12. Direct hybridization analysis using specific oligonucleotide probes demonstrates that the mutation is tightly associated with a specific restriction fragment-length polymorphism haplotype among mutant alleles. The splicing mutation is the most prevalent phenylketonuria allele among Caucasians, and the results suggest the possibility of detecting carriers of the genetic trait who have no family history of phenylketonuria.

CLASSICAL phenylketonuria (PKU) is an autosomal recessive human genetic disorder caused by a deficiency of hepatic phenylalanine hydroxylase (PAH, phenylalanine 4-monooxygenase, EC1.14.16.1). In the normal human liver, PAH catalyses the rate-limiting step in the hydroxylation of phenylalanine to tyrosine. The reduction in PAH activity causes an accumulation of serum phenylalanine, resulting in hyperphenylalaninaemia and abnormalities in the metabolism of many compounds derived from the aromatic amino acid. PKU is the most common inborn error in amino-acid metabolism. Its incidence among Caucasians ranges from 1:4,500 in Ireland to 1:16,000 in Switzerland, with an average incidence of about 1:8,000 in the United States. The mutant gene frequency is such that 1 in 50 Caucasians is a carrier of the disease trait. Without early detection of PKU, followed by rigid implementation of a restricted diet low in phenylalanine during the first decade of life, affected

children develop severe mental retardation (for reviews see ref.

Although neonatal screening for PKU is routinely carried out in Western countries, there has been no conventional means of identifying affected fetuses. We used a full-length human PAH complementary DNA clone⁴ to identify and map eight restriction fragment-length polymorphisms (RFLPs) at the human PAH locus⁵⁻⁷. These RFLPs segregate in a mendelian manner and concordantly with the mutant alleles in PKU kindreds. The frequency of the RFLPs in the PAH gene is such that the observed heterozygosity in the general population is about 87% (ref. 8). Thus, prenatal diagnosis can be performed in most PKU families by RFLP analsis9. However, the analysis is limited in that it can only be used in families with a history of PKU.

We recently used RFLPs to identify 12 haplotypes of normal and PKU alleles in the Danish population, and observed a h

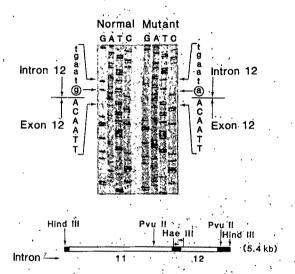

Fig. 1 Identification of a PKU splicing mutation. a, Physical map of the mutant gene. The maps of five overlapping cosmid clones (cPKU 17, cPKU 14, cPKU 30, cPKU 13 and cPKU 23) were used to characterize the mutant gene. The subcloned EcoRI fragments containing exon sequences were used for Sanger dideoxynucleotide sequence analysis as described previously for the normal PAH gene? The detailed structure of the mutant gene in the 5' to 3' orientation and the location of RFLP sites are also shown. The cosmid library construction and gene characterization were carried out as described previously. b, Sequence analysis of the 5'-donor splice site of exon 12. The 114-base-pair (bp) HaeIII fragment (bottom) containing 90 bp of exon 12 and 24 bp of the downstream intron was inserted into the SmaI site of M13mp18¹⁹ and sequenced in both directions (arrows) by the dideoxynucleotide chain-termination method 18. A comparison of the normal and mutant sequence at the intron/exon border illustrates the single base substitution.

strong association among distinct RFLP haplotypes and PKU alleles. A close association has been observed previously between RFLP haplotypes of the β -globin locus and specific β -thalassaemia mutations in different ethnic populations (for review see ref. 10). Whether such tight association between RFLP haplotypes and specific mutations exists in PKU due to linkage disequilibrium can be verified only by molecular analysis of the mutant genes. Having established the molecular structure and RFLP haplotype linkage map of the PAH gene⁷, this important issue can be addressed by cloning and characterizing the mutant PAH alleles of the prevalent RFLP haplotypes.

Isolation and sequencing of a mutant PAH gene

RFLP haplotypes for both PKU and normal PAH genes have been determined for 33 informative Danish PKU families. About 75% of the normal and 90% of the mutant PAH genes are confined to four common RFLP haplotypes (Table 1; haplotypes 1, 2, 3 and 4). Thirty-eight percent of the mutant alleles have a single haplotype (haplotype 3) that is relatively rare among the normal gene pool (3%). A cosmid genomic

DNA library was thus constructed from leukocyte DNA isolated from a PKU individual who is homozygous for haplotype 3. The library was screened with a full-length human PAH cDNA probe⁴ and several corresponding genomic clones were isolated (Fig. 1a). To identify the mutation causing PKU, exoncontaining regions of the gene were subcloned into the vector M13mp18 for sequence analysis. The mutant gene sequence is identical to that of the normal PAH gene reported previously⁷ except for a silent nucleotide substitution ($A \rightarrow G$) in the third base of codon 232 ($G\ln$)⁴⁻⁷, and a G to A transition at the 5' splice donor site of intron 12, altering the obligatory G-T donor dinucleotide to A-T (Fig. 1b). Gene transfer and expression experiments demonstrated that this mutation results in abnormal processing of PAH mesenger RNA and loss of PAH activity (J.M. et al., unpublished results).

Design and testing of probes

Figure 2b shows the nucleotide sequence at the mutation site in the gene; this did not result in any alteration in restriction recognition sequence from the normal PAH gene. Since a single base-pair mismatch is sufficient to destabilize duplex structures

Table 1 RFLP haplotype distribution of the PAH alleles in Denmark

	Normal	alleles	Mutant alleles

* Number of alleles observed in a total of 66 chromosomes analysed. All tested families were Caucasian and had no history of consanguinity. Clinical criteria of the probands as affected PKU individuals and parents as heterozygotes in the families have been reported previously¹⁵.

in DNA hybrids^{11,12}, oligonucleotide probes can be used to distinguish between normal and mutant alleles in the human genome. Thus, we synthesized a normal-specific probe (21-mer) which is complementary to the sense-strand of the normal gene (Fig. 2b) and forms a C-A mismatch at the mutation site with the mutant gene. For the mutant-specific probe, a 21-mer of the sense-strand sequence was synthesized. At the mutation site this probe forms a C-A mismatch with the normal gene sequence (Fig. 2b).

The fidelity of the two oligonucleotide probes in detecting the respective sequences was then tested using the normal and mutant genomic DNA clones. Due to the high A+T contents of the normal and mutant probes (76% and 81%, respectively), we used the base-composition-independent oligonucleotide hybridization method^{13,14} to analyse the point mutation. *PvuII* digestion of the 12-kilobase (kb) *EcoRI* fragment isolated from both the normal (N) and mutant (M) gene clones generated a 2-kb fragment containing the entire exon 12 plus flanking intronic sequences. Under the hybridization conditions used, the normal probe hybridized only to the 2-kb *PvuII* fragment of the normal gene (Fig. 2a, middle panel), and the mutant probe hybridized specifically to the mutant gene (Fig. 2a, right panel).

Mendelian segregation of PAH alleles

Using the appropriate hybridization conditions described in Fig. 2 legend, the synthetic oligonucleotide probes were used to identify the mutant alleles in genomic DNA and to analyse their segregation in PKU kindreds. The first family analysed was the one from which the mutant allele had been isolated and characterized. In this family, both parents contain a mutant haplotype 3 gene which hybridized to the mutant probe (Fig. 3a, lanes 1, 2), suggesting that both mutant alleles in this family may contain the same mutation. Since this disorder is autosomal recessive in nature, both parents are obligate carriers of the PKU trait and both must also contain a normal gene. In this case, both normal alleles in the two parents corresponded to haplotype 4, and both hybridized to the normal probe as expected (Fig. 3a, lanes 7, 8). There are two affected individuals in this family; both are homozygous for the mutant haplotype 3 alleles which hybridized strongly to the mutant probe (Fig. 3a, lanes 3, 4), but not to the normal probe (Fig. 3a, lanes 9, 10).

The results confirm that both mutant alleles in this family contain the same mutation. An unaffected sibling in this family is homozygous for the normal haplotype 4 alleles which hybridized to the normal probe (Fig. 3a, lane 11) but not to the mutant

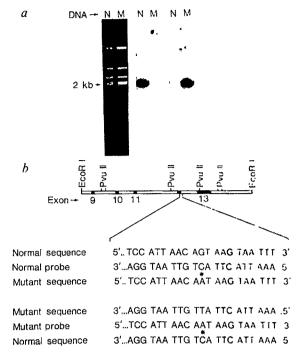

Fig. 2 Oligonucleotide specificity for the detection of the PKU mutation in cloned DNA by direct-gel hybridization. a, The 12-kb EcoRI fragment containing exons 9 to 13 was isolated from normal (N) (ref. 7) and mutant (M) cosmid clones and inserted into plasmid pBR322. PvuII plus EcoRI digests of the recombinant clones were electrophoresed on 1% agarose gels, stained with ethidium bromide (left panel), and processed for direct-gel hybridization as described previously11. Dried gels were hybridized to oligonucleotide probes specific for normal (middle panel) and mutant (right panel) cloned PAH genomic DNA sequences. Exon 12 plus flanking intronic sequences are contained in a 2-kb Prull fragment. The gels were overexposed intentionally in order to demonstrate the differential hybridization signals generated by the two oligonucleotide probes. b, Oligonucleotide probes used to detect the normal and mutant 5'-donor splice site of exon 12. The asterisks denote the C-A mismatch between the normal probe and mutant gene sequence, and the mutant probe and normal gene sequence.

Methods. Oligonucleotides were synthesized by an automated (SYSTEC, Inc.) solid-phase phosphite triester method. High specific activity probes (1010 c.p.m. µg-1) were generated by the primer extension method¹². The normal probe was synthesized on a 21-base template (5'-TCCATTAACAGTAAGTAATTT-3') by hybridized 9-base primer (3'-TTCATTAAA-5'), while the mutant probe was synthesized by extension of a 9-base primer (5'-TCCAT-TAAC) hybridized to a 21-base template (3'-AGGTAATTGTTATTCATTAAA-5'). Dried gels were hybridized overnight at 37 °C in 6×NET (0.9 M NaCl, 6 mM EDTA, 0.5% SDS and 0.09 M Tris, pH 7.5) containing 0.2 mg of salmon sperm DNA and 2×106 c.p.m. of probe per ml of hybridization solution¹⁴. The gel membranes were then washed twice at 0 °C for 30 min in TMA (3 M tetramethylammonium chloride (Aldrich), · 2 mM EDTA and 50 mM Tris pH 8.0), once each at 23 °C (30 min) and 60 °C (7 min) in TMA containing 0.2% SDS, and at 23 °C for 30 min in TMA¹⁴. The gel strips were then autoradiographed between two Quanta III intensifier screens (Dupont) at -80 °C.

probe (Fig. 3a, lane 5). As expected, a second unaffected sibling in this family who is heterozygous for mutant haplotype 3 and normal haplotype 4 alleles hybridized to both the mutant and normal probes (Fig. 3a; lanes 6 and 12, respectively). Thus the oligonucleotide hybridization analysis not only was able to detect the specific mutation in genomic DNA, but also demonstrated concordant segregation of the normal and mutant alleles in this PKU family.

To verify that the mutation is not a constitutive part of the normal haplotype 3 allele, we analysed a PKU family possessing

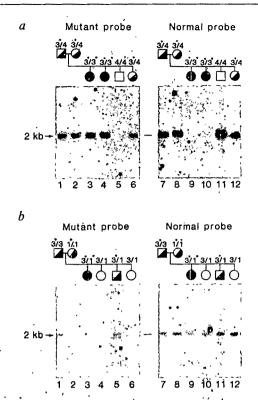

Fig. 3 Oligonucleotide hybridization analysis of two Danish PKU families. In both families, the probes used for lanes 1-5 and lanes 7-12 were the mutant and normal oligonucleotides, respectively. Squares, male; circles, female; open symbols, normal haplotype; solid symbols, mutant haplotype; a, Lanes 1 and 7, father; lanes 2 and 8, mother; lanes 3, 4, 9, 10, two affected children; lanes 5, 6, 11, 12, two unaffected children, b, lanes 1 and 7, father; lanes 2 and 8, mother; lanes 3 and 9, proband; lanes 4-6 and 10-12, three unaffected siblings. DNA was isolated from leukocytes of family members, digested with PvuII and analysed by dried-gel hybridization as described in Fig. 2 legend. The segregation of the PKU alleles (*) and the appropriate RFLP haplotypes are shown at the top of each autoradiograph.

both normal and mutant haplotype 3 alleles. The father in this family, who is homozygous for haplotype 3 but an obligate carrier of the PKU trait, possesses a mutant haplotype 3 allele which hybridized to the mutant probe (Fig. 3b, lane 1) and a normal haplotype 3 allele which hybridized to the normal probe (Fig. 3b, lane'7). The results demonstrated conclusively that the splicing mutation is not a constitutive part of the normal haplotype 3 alleles per se. In contrast, the mother possesés normal and mutant haplotype 1 PAH alleles. The mutant probe did not hybridize to DNA isolated from this individual (Fig. 3b, lane 2), while the normal probe did (Fig. 3b, lane 8). The data indicate that the PKU mutation associated with the haplotype 1 allele in this family is not the same as that identified in the mutant haplotype 3 allele. The proband in this family, having inherited a mutant haplotype 3 allele from the father and a mutant haplotype I allele from the mother, hybridized to both the mutant and normal probes (Fig. 3b, lanes 3, 9). This individual apparently contains two different mutant alleles and is thus a compound heterozygote.

Carrier detection by oligonucleotide analysis

Our hybridization analysis of the above family also illustrated the feasibility of using the mutant probe to detect carriers of the PKU trait. There are three phenotypically normal siblings in addition to the proband in that family. Since both parents are haplotype homozygotes (1/1 and 3/3), all offspring are haplotype heterozygotes (1/3) and the RFLP haplotype analysis is therefore totally non-informative. The observed 'normal'

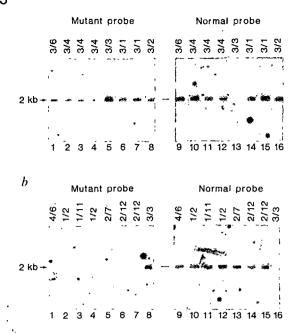

Fig. 4 Oligonucleotide hybridization analysis of Danish PKU individuals of defined RFLP haplotypes. DNA was isolated from leukocytes of PKU individuals and analysed using mutant (lanes 1-8) and normal (lanes 9-16) oligonucleotide probes as described in Fig. 2 legend. a, Haplotype 3 genotypes; b, non-haplotype 3 genotypes. The previously characterized RFLP haplotypes are shown at the top of each lane.

phenotypes in the unaffected siblings can result from three genotypes: normal haplotype 3/normal haplotype 1; mutant haplotype 3/normal haplotype 1; and mutant haplotype 1/normal haplotype 3. These genotypes can be partially distinguished by direct analysis of the splicing mutation site within the gene. DNA from one of the siblings hybridized to the mutant oligonucleotide (Fig. 3b, lane 5), suggesting that this individual has inherited the mutant haplotype 3 allele from his father and the normal halplotype 1 allele (Fig. 3b, lane 11) from his mother, and must therefore be a carrier of the PKU trait. In the absence of information for the haplotype 1 mutant gene sequence, the carrier status of the other two siblings cannot yet be fully determined. Nevertheless, the possibility that they have also inherited the mutant haplotype 3 allele from their father is excluded by the negative hybridization data obtained with the mutant oligonucleotide probe (Fig. 3b, lanes 4, 6).

Mutation frequency and haplotype association

We next determined the frequency of the splicing mutation and the degree of its association with haplotype 3 in the Danish population. RFLP haplotype analysis of 33 informative PKU families (66 normal and 66 mutant PAH chromosomes) provided a repertoire of mutant alleles for such an analysis (Table 1). Genomic DNA samples isolated from all PKU individuals containing a mutant haplotype 3 allele hybridized to the mutant probe (Fig. 4a, lanes 1-8). One PKU individual possesses two copies of the mutant haplotype 3 allele, and his DNA hybridized more strongly to the mutant probe (Fig. 4a, lane 5). The results suggested that all mutant haplotype 3 alleles in Denmark contain the same mutation in the PAH gene.

Although the homozygous haplotype 3 patient showed no hybridization with the normal probe as expected (Fig. 4a, lane 13), the normal probe did hybridize to all mutant alleles in the remaining individuals who possess non-haplotype 3 chromosomes (Fig. 4a, lanes 9-12, 14-16). Another group of PKU individuals possessing various non-haplotype 3 mutant alleles were also analysed. DNA isolated from these individuals did not hybridize to the mutant probe (Fig. 4b, lanes 1-7), while

ND, not determined due to lack of DNA samples.

strong hybridization signals were obtained with the normal probe (lanes 9-15). As controls in these experiments, we included DNA isolated from a homozygous haplotype 3 PKU individual: this hybridized to the mutant probe (Fig. 4b, lane 8) but not to the normal probe (lane 16). Our experiments strongly suggest that the mutations in all non-haplotype 3 alleles are distinct from the G-T to A-T transition mutation present in the mutant haplotype 3 allele.

Table 2 summarizes the population genetic data. A total of 91% (60 out of 66) of the available PKU chromosomes and 27% (18/66) of the available normal chromosomes were analysed with the mutant and normal oligonucleotide probes. All mutant haplotype 3 alleles hybridized with the mutant probe and none hybridized with the normal probe (Table 2). The remaining mutant alleles of other haplotypes and all of the normal alleles hybridized specifically with the normal probe. The results demonstrate unambiguously that the splicing mutation is specifically associated with the mutant haplotype 3 alleles, and the association is both inclusive and exclusive.

Discussion

Although PKU appears to be a heterogeneous disorder at the clinical level, controversy has persisted over whether this heterogeneity results from multiple mutations in the PAH gene varying in their degree of severity (for review see ref. 15). We recently reported that the cause of the disease must be heterogeneous because PAH mRNA was detected in some, but not all, PKU liver biopsy specimens¹⁶. Liver-specific expression of the PAH gene in man and the general lack of hepatic tissues of sufficient quantity and quality has precluded study of the molecular basis of PKU at the mRNA and protein levels. Having recently established the normal PAH gene structure, however, PKU mutations can be identified at the genomic DNA level by characterization of the mutant genes.

Extensive RFLP halplotype analysis of the PAH locus in the

Danish population provided the theoretical basis for selection of mutant alleles for molecular characterization. It is interesting that 90% of the PKU genes in the Danish population are confined to four common haplotypes. We have reported here the molecular cloning of a mutant PAH gene associated with haplotype 3, which comprises 38% of all mutant alleles in the Danish population. Sequence analysis of this gene demonstrated a single base substitution at the 5' splice donor site of intron 12. Expression studies using the mutant sequence has demonstrated that the mutation causes aberrant RNA splicing by skipping exon 12 in the mature mRNA, and the mRNA is translated into a truncated protein product that is unstable in the cell (J.M. et al. unpublished results). DNA hybridization analysis using an oligonucleotide probe specific for the genetic lesion demonstrated an absolute association of this mutation with the mutant haplotype 3 alleles in the Danish population. The results strongly suggest that the G-T to A-T mutation occurred relatively recently on a normal haplotype 3 gene and spread in the Danish population by a founder effect. In addition, the specific mutation is not present in mutant alleles of other haplotypes, providing unambiguous evidence that there are multiple and distinct mutations in the PAH gene which are reponsible for PKU.

Since PKU frequency among Caucasians is the highest in Ireland and progressively less prevalent throughout northern and southern Europe, it has been proposed that the PKU allele is of Celtic origin and spread to various European populations¹⁷ Using the mutant-specific probe to analyse DNA samples of PKU kindreds from various European countries, we have obtained preliminary evidence that the splice donor site mutation of intron 12 is also present in England, Ireland, Scotland, Switzerland and Italy (data not shown). In those families that are informative for RFLP haplotype analysis, the association between the specific mutation and RFLP haplotype 3 is also preserved in these populations. Thus, the data suggest the spread of a single mutant haplotype 3 chromosome in the Caucasian race by founder effect.

The future characterization of PKU mutations arising on the other prevalent haplotypes (haplotypes 1, 2 and 4) will clarify whether PKU is caused by a limited number of mutations that spread throughout the Caucasian race or whether multiple PKU mutations arose independently in various population backgrounds. Such a study will provide insight into the evolution and molecular origin of mutations in the PAH gene which cause PKU. If such studies confirm our hypothesis regarding the linkage of specific mutations and RFLP haplotypes in the PAH locus, it should be possible to design a cassette of oligonucleotide probes to detect 90% of the mutation chromosomes in the Caucasian population and provide a potential molecular means for PKU carrier detection in individuals with no family history of PKU.

We thank Ms Kelly Brayton for technical assistance, Mr David Nunn for the synthesis of specific oligonucleotides, and Ms Kelly Porter for typing the manuscript. Effect of gravitational lenses on the microwave background, and 1146+111B,C

Jeremiah P. Ostriker* & Ethan T. Vishniac†

* Princeton University Observatory, Princeton, New Jersey 08544, USA † Astronomy Department, University of Texas, Austin, Texas 78712, USA

We suggest a simple check of the proposal by Turner et al. that the pair of quasars 1146+111B,C are, in fact, two images of the same object lensed by an intervening object. If the lens is a cluster, either of normal galaxies or of dark matter, the microwave background seen through the cluster will be distorted by the Zeldovich-Sunyaev effect at the 10⁻³ level.

A new and exceptional candidate for an astronomical gravitational lens system has been found by Turner et al.1. Two quasars separated on the sky by 157 arcs have very similar spectra and redshifts agreeing to within 100 km s⁻¹. If confirmed by further observations, this would be by far the largest angular splitting observed. Galaxies in clusters will typically produce a splitting of ~3 arcs (ref. 2), not far from the average of the six known systems, which is 4 arc s. As the splitting angle is proportional to $(v_{\parallel}/c)^2$, where v_{\parallel} is the internal one-component velocity dispersion and c is the velocity of light, clusters of galaxies can produce far larger splittings. In fact, on this basis Paczynski³ proposed that the 1146+111B,C pair might be such a lens system before the recent observations.

This system, if it is a gravitational lens, may have been produced by a massive black hole⁴ or by a cosmic string⁵, but it is worth exploring the more conventional possibility that it arises from an intervening cluster of matter. We now show that, if a cluster has acted as a gravitational lens, it is essentially guaranteed that it will also produce an observable Zeldovich-Sunyaev effect. The new lens system corresponds to a very large and detectable effect. This is not surprising, as typical clusters can produce a nearly detectable effect, and this lens system would require an unusual cluster.

Turner et al.² showed that, under normal circumstances, the production of a double image requires a projected mass distribution (on the plane of the sky) greater than Σ_c , where for a universe with density parameter $\Omega_0 = 1$

$$\Sigma_{c} = \frac{cH_0}{8\pi G} \frac{x^2(y^{1/2} - 1)}{(y^{1/2} - x^{1/2})(x^{1/2} - 1)}$$
(1)

where $y = 1 + z_Q$ and $x = 1 + z_L$ are the redshifts of the quasar and the lens, respectively, $H_0 = 100h \text{ km s}^{-1} \text{ Mpc}^{-1}$ is the Hubble constant, and G is the universal gravitational constant. This surface density is of order 1 g cm^{-2} , and thus the optical depth to electron scattering (τ_{es}) is likely to be significant for all gravitational lens systems. If the ratio of baryonic mass to total mass is f_b , and the matter in the lens has normal composition, and is ionized, then

$$\tau_{\rm es,c} = 0.35 f_{\rm b} h \Sigma_{\rm c} \tag{2}$$

so that, if $\Sigma > \Sigma_c$, then $\tau_{\rm es} > \tau_{\rm es,c} \simeq 1$. The angular splitting $(\Delta \theta)$ for an isothermal distribution of mass is, for the chosen cosmology²,

$$\Delta\theta = (v_{\parallel}/c)^2 8\pi \frac{y^{1/2} - x^{1/2}}{x^{1/2}(v^{1/2} - 1)}$$
 (3)

For an isothermal sphere with gas in equilibrium with the same distribution as the gravitating mass, $v_{\parallel}^2 = C_s^2$, where c_s is the speed of sound, we will take as a general result that

$$c_{\rm s}^2 \equiv \beta v_{\parallel}^2 \tag{4}$$

Finally, the Zeldovich-Sunyaev effect for temperature fluctuations in the microwave background can be written as

$$\Delta T/T = -2.2 \times 10^3 c_{\rm s}^2 / c^2 \tau_{\rm es} \tag{5}$$

in the long-wavelength limit.

Combining equations (1)-(5) we obtain

$$|\Delta T/T| \ge |(\Delta T/T)c| = 1.78 f_b \beta \Delta \theta h g(x, y)$$
 (6)

where

$$g(x, y) = \frac{x^{5/2}(y^{1/2} - 1)^2}{(y^{1/2} - x^{1/2})^2(x^{1/2} - 1)}$$

For the case at hand, y = 2.01. The minimal value of g(x, y) occurs, for a fixed quasar position y, at $x = [y^{1/2} + 3/4 - ((4y^{1/2} +$ $(3)^2 - 40y^{1/2})^{1/2}/4$. In this case this is x = 1.20, which gives a value of g(x, y) = 27.8. Therefore, for the system 1146 + 111B,C where $\Delta\theta = 157$ arcs, we find

$$|\Delta T/T| \ge 0.038\beta f_{\rm b}h\tag{7}$$

From light-element nucleosynthesis, the fraction of the critical density contributed by baryons, $\Omega_b \approx 0.03 \ h^{-2}$ (ref. 6), so that if $f_b = \Omega_b$, then $|\Delta T/T| = 1.2 \times 10^{-3} \beta/h^{-2}$, which should definitely be detectable. For the more likely value of x = 1.5, the numerical coefficient is larger by a factor of ~ 1.77 .

This calculation has assumed that the cluster has the shape of an isothermal sphere. Is this a fair assumption? The relationship between the angular splitting and the surface density of material is relatively insensitive to the shape of the cluster. However, if the cluster is elongated towards the observer, then the integrated electron pressure is no longer simply related to the angular splitting. This is the significance of the factor β in our calculation. Assuming we are observing lensing due to a prolate spheroid pointed at us with an axis ratio <1, then β is roughly proportional to the value of the axis ratio. For an average lens system we can be confident that this will not greatly lower our estimate of the induced temperature distortion. For the particular case of 1146+111B,C we have no basis on which to constrain the axis ratio.

Suppose that the region has, for some reason, excluded gas, or that the gas has been kept cold, or that f_b is in fact quite small. In this case, there will be no electrons in the intracluster gas and therefore no Zeldovich-Sunyaev effect. There will still be an effect on the microwave background due to the mass concentration. This is due to purely gravitational effects on the background photons as they traverse the lens system. This effect is approximately given by $|\Delta T/T| = (\Delta \theta)^2$ (see ref. 7), which in this case gives a temperature distortion of $\sim 6 \times 10^{-7}$. This is smaller than present limits on detectability.

We see that an unusual cluster of a normal type would produce a large effect. Even if the cluster were made of dark matter without galaxies, but contained baryons in a normal ratio, the effect would be undiminished. In the unlikely event that the cluster were devoid of hot gas or of some very unusual shape so that the normal effect were absent, there would still be an effect not far below our present ability to look for temperature distortions. These results suggest that the microwave background at the lens system 1146+111B,C, and any other lens candidates with large separations, necessarily provide us with an independent way of confirming their status as gravitational lenses.

We thank Edwin L. Turner for helpful comments. This work was supported by NSF grant AST-8451736 and NASA grant NAGW-765.

Observations of the cosmic background radiation near the double quasar 1146 + 111B,C

Antony A. Stark, Mark Dragovan, Robert W. Wilson & J. Richard Gott III

AT&T Bell Laboratories, Holmdel, New Jersey 07733, USA Princeton University Observatory, Princeton, New Jersey 08544, USA

Paczynski¹ and Turner et al.² have suggested that the extraordinary double quasar 1146+111B,C found by Hazard et al.3 is a possible gravitational lens. The hypothetic lensing object is unknown. If the lensing object is a cluster of galaxies4 or a cosmic string5,6, it may cause observable effects in the cosmic background radiation. At millimetre wavelengths, a cluster would be expected to cause a reduction in the temperature of the background in the vicinity of the cluster as the result of the Zeldovich-Sunyaev effect. The area of sky on one side of a cosmic string would have a different radiation temperature from that on the other side. If either of these expected signatures were seen in the cosmic background, it would be strong evidence in favour of that hypothesis. We have searched for microwave background inhomogeneities near 1146+ 111B,C. An east-west strip of sky, 16 arc min long and centred on the point between the quasars, was observed with a beam of diameter 105 arcs at 3 mm wavelength. Our observations show only noise with an r.m.s. noise level of 0.0010 K. These observations set limits on the properties of the lensing object if it is a cosmic string or a cluster of galaxies, and we do not confirm either hypothesis.

Observations were made for 4-h periods on each of seven nights in March and April 1986, using the 7-m-diameter antenna at AT&T Bell Laboratories, Crawford Hill. At 100 GHz, this antenna has a beam efficiency of 0.92 and a beam size of 105 arc s (full width at half maximum). The receiver is a superconductorinsulator-superconductor (SIS) mixer followed by an FET (field-effect transistor) amplifier with 512 MHz bandwidth. Double-sideband receiver temperatures were typically 90 K, and the total system temperature including atmospheric corrections was 180-300 K. The receiver gain and noise were measured every half hour by chopping between a liquid-nitrogen-cooled absorber and a room-temperature absorber. The sky temperature was measured by chopping between the sky and the liquid nitrogen absorber, which allows a calculation of the atmospheric opacity.

The observing method was a beam-switched drift scan, as described by Radford et al.7. As the source moved across the sky, the antenna was driven to a position ahead of the source and then held stationary with respect to the Earth. The observed strip would then drift through the beam. To eliminate the effect of gain fluctuations, the receiver was chopped at a frequency of 15 Hz between the primary beam and a reference position at 30 arc min greater azimuth, so that the observed value of a point on the strip is the difference in antenna temperature between that point and the reference position. The time series that resulted from each drift scan was binned at intervals corresponding to 1 arc min on the sky, slightly larger than half a beam-width. Many drift scans were averaged to yield the plot in Fig. 1. The reference positions changed as the source moved across the sky, because of field rotation. The chopping was done with a rotating blade at the Cassegrain focus8. Before each night's observations the system was checked by drift-scan observations of calibration sources with known millimetre-wave fluxes.

The results are shown in Fig. 1. Here, all the drift-scans have been averaged. None of the data have been discarded. Figure 1 shows corrected antenna temperature as a function of position along the strip. The zero-point of the temperature scale has been arbitrarily set so that the average value along the strip is zero;

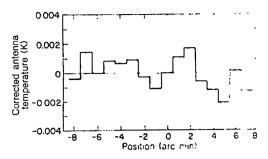

Fig. 1 Corrected antenna temperature at 100 GHz as a fail of the of position along a constant declination strip passing by tween the quasars 1146+111B,C. The 0 arc min position s 11 " 46 min 06 s, $\delta_{1950} = 11^{\circ}$ 05' 28". West is to the left, east to the right

therefore, the data do not show possible different as between the strip and the reference positions. However, a step or a stepe in the brightness as a function of position along the strip would appear in the plot.

These data seem to be random. The r.m.s make level is 0.0010 K. If the lensing object is an isothermal chatter there is a predicted⁴ Zeldovich-Sunyaev dip of $\Delta T = 7.003 \text{ is }^{-10}$: centred on the 0 arc min position in Fig. 1, where 9 is geometrical factor of order unity, f is a factor of order g at that measures the fraction of the mass in the for: of ion and gas $(f \equiv M_{\text{ionized}}/[0.03 \ M_{\text{virtal}}];$ for the Coma cluste $f = 10^{\circ} \text{ nd}$ $h \equiv H_0/100 \text{ km s}^{-1} \text{ Mpc}^{-1},$ where H_0 is the Hubble cone for -10° the lensing object is a stright cosmic string there is a produced step of $\Delta T \approx 0.002 \text{ K} \text{ v}_s/c$ of either sign where v_s is the schools of the presumably relativistic string perpendicular to its length and to our line of sight. The step could be located anywhere from position -3 to +3 arc min, because the stong might be anywhere between the quasars. It would be or adenee 5. ~2 beam-widths because the position angle of the samp is reast likely to be 63°, that is, perpendicular to the line between the quasars. Both a cluster and a string would be expected to a leaf several of the independently measured points on our spilits strip, so the statistical significance of our non-detection is grower than the noise in any single point. The data are consistent with a limit of $\beta fh^{-2} \le 0.3$ for the cluster. The hypothetical cluster would then have to be relatively poor in ionized gan the feature $M_{
m ionized}/M_{
m virial}$ would be one third of the Coma cluster v. Hz The data are also consistent with a limit of $v_i \in 0$ between is the speed of light) for the case of a string. A string would no expected⁵ to have $v_s = 0.5$ c, so our measurment does not also out the string hypothesis, but this measurement or istrains the properties of the string. For example, the apparent projected angle, x, between the string and the normal to the line between the quasars is given by $^6 \tan(\chi) = (v_s/c) \tan(\alpha)$, where α is the angle between the string and the plane of the sky

The data are, of course, also consistent with the negative hypothesis that B and C are two different quasars that coincidentally have very similar spectra, and that there is no lens a, all At the 3σ level of statistical significance, there is no effect on scales of ≥105 arcs at a level of 10° of the cosmic background radiation.

We thank R. E. Miller for the SIS junction used in the reciver, and W. H. Bent for contributions to instrumentation on the 7-m antenna.

The chemical evolution of the Galaxy

Gerard Gilmore* & Rosemary F. G. Wyse†

* Institute of Astronomy, Madingley Road, Cambridge CB3 0HA, UK † Space Telescope Science Institute, Baltimore, Maryland 21218, USA

The distribution of enriched material in the stars and gas of our Galaxy contains information pertaining to the chemical evolution of the Milky Way from its formation epoch to the present, providing general constraints on theories of galaxy formation. Detailed studies of the metallicities of well-defined samples of long-lived G-dwarf stars in the solar neighbourhood have ruled out the 'simple closed-box' model of galactic chemical evolution-too few very metal-poor stars are observed 1-3. The weakest assumption inherent in this model is that the galactic disk formed and evolved as a closed system. Allowing accretion of gas, either metal-enriched or primordial (the latter requiring a particular dependence of star formation on gas density), can yield an improved fit to the observations³. However, secondary infall from the galactic extreme spheroid provides only a slight alleviation of this 'G-dwarf problem'4. Here we show that consideration of the chemical properties of the thick-disk population of the Galaxy^{5,6} results in a selfconsistent model for galactic chemical evolution.

Motivation for the closed-box model for the galactic disk came from the proposal⁷ that the formation of the spheroid of the Galaxy, and the collapse of residual gas to a thin disk, was extremely rapid, having been largely completed in a free-fall time. However, recent evidence from in situ observations of a stellar component of the Galaxy with kinematics and metallicity distribution intermediate between those of the extreme spheroid and thin disk^{5,6,8-11} has shown that this picture of Galaxy formation and evolution is oversimplified. Here we investigate the metal-enrichment history of an evolutionary sequence in which a short-lived phase of rapid star formation forms the extended, metal-poor, pressure-supported extreme spheroid, with the thick disk forming subsequently before a final equilibrium state is attained, the centrifugally supported thin disk forming over a long timescale once the Galaxy potential is unperturbed and steady^{6,12,13}

The transition between extreme spheroid and thick disk can be investigated using the two-zone model⁴. Thus, we assume that gas is removed from the spheroid star formation process at a rate which is a constant multiple, denoted by c, of the star formation rate. This may be expected if the gas is heated by supernova explosions, and within the context of the modified simple model has the same effect as a lowered nucleosynthetic yield4. We keep the remaining major assumptions of the simple model; namely, that the stars enrich the gas instantaneously and that the system is well mixed and chemically homogeneous. The parameters in the model have standard values: solar neighbourhood yield¹⁴ and stellar initial mass function¹⁵, with a lock-up fraction of gas into stars of 0.6-0.8 (ref. 16). For the extreme spheroid, we also keep the assumption of zero initial metallicity, in keeping with the most recent derivation of the metallicity distribution of extremely metal-poor spheroid stars¹⁷

The theoretical cumulative metallicity distribution, whose form in the adopted model is independent of the unknown star formation rate, may be compared with observations to solve for the value of the constant c. We have used the metal-poor galactic globular clusters to define the observed extremespheroid metallicity distribution (Fig. 1a). This distribution is in excellent agreement with that derived by Sandage 10 for his

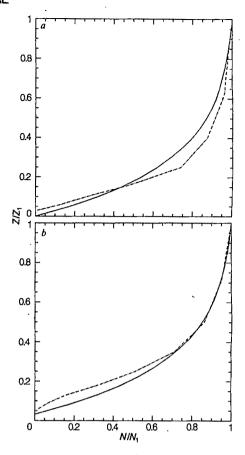

Fig. 1 Comparison of observed (dashed lines) and predicted (solid lines) cumulative metallicity distributions for the extreme spheroid⁸ (a) and thick disk^{6,10,11} (b). Plots show the total number, N, of tracers with metallicity $\leq Z$, normalized to the maximum abundance, Z_1 . In a, the observed distribution⁸ is defined by the metal-poor ([Fe/H] < -0.8) galactic globular clusters; the model shown model has c = 10. In b, the observed log metallicity distribution has been approximated by a truncated gaussian ($\pm 2\sigma$), with mean [Fe/H] = -0.6, σ = 0.3; the model shown has c = 1.

J1

large, kinematically defined sample of subdwarf stars. Norris11 has shown that this distribution represents the true metallicity structure of the extreme spheroid, independent of the detailed selection criterion for the sample. For the adopted stellar nucleosynthesis parameters, these data are fit well by removal of gas from the star-forming process at a rate ~5-20 times the spheroid star formation rate (see refs 4, 18, 19). The uncertainty in c results from the possible range of the lock-up fraction in the extreme spheroid, and from the observational spread; the use of the cumulative metallicity distribution forces a smooth distribution through the observations. These values of c yield an average metallicity of the residual gas of $[Fe/H] = -1.4 \pm 0.2$. (As the gas removed from the spheroid star-forming process is, as usual, assumed to be well mixed and enriched with stellar ejecta with a time-independent, solar distribution of elements, the time-averaged metallicity is most meaningful.) This metallicity is in excellent agrement with the metal-poor tail of the thick-disk stars^{6,9,11}, but is much too metal-poor for the thin-disk stars—showing explicitly that an initial enrichment due to rapid infall from the extreme spheroid cannot alone provide a resolution of the thin-disk G-dwarf problem⁴.

In the present model, the residual gas after spheroid star formation ceases is treated as simply providing the proto-thick disk with a non-zero initial metallicity, equal to the mean gas enrichment found above. This treatment is consistent with the high star formation rate suggested by the extreme-spheroid kinematics and the rapid removal of all gas from the spheroid

star-formation process in the present model (c = 5-20). As the thick-disk metallicity distribution overlaps that of the extreme spheroid at the metal-poor end, and that of the thin disk at the metal-rich end, one must be careful to ensure minimal intercomponent contaminations. The thick disk may be defined in three ways, the first by a volume sample in situ above the galactic plane, where it is expected to dominate⁶, the second kinematically10, and the third by a combination of spectroscopic and kinematic data11. These three determinations are in good agreement, so that the adopted metallicity structure is not sensitive to a specific criterion. Additionally, the most recent analogous determinations of the thin-disk metallicity structure^{6,10,20} show that there is no difficulty in isolating the thick- and thin-disk parameters with sufficient precision for the present problem.

Figure 1b shows the cumulative metallicity distribution for thick-disk stars^{6,10,11}. The best-fitting theoretical curves have net outflow parameter c = 1-2, and a corresponding mean value of the metallicity of the ejecta from thick to thin disks of [Fe/H] = -0.6 ± 0.1 . This level of pre-enrichment agrees well with the metallicity determined for the oldest, most metal-poor Gdwarfs^{3,6}. Hence, inclusion of the thick disk in this simple model resolves the G-dwarf problem for thin-disk stars in the solar neighbourhood.

Pre-enrichment of the thin disk was recognized previously3,16 as a resolution by itself to the G-dwarf problem. For the present model, detailed calculations show that the cumulative metallicity distribution for thin-disk stars limits any infall of un-enriched material following the prompt enrichment by the thick-disk ejecta to a rate of <0.2 times the star formation rate, assuming constant relative rates, as may be expected14. This is in agreement with limits on present-day high-velocity infall²¹. Constraints on our model from other quantitites, such as the age-metallicity relation and the age-velocity dispersion relation for long-lived thin-disk stars, are weak, as the two recent calibrations of these relations 12,20 are in significant disagreeement. The apparently extremely-high-metallicity K-giants found in the direction of the galactic centre²² are difficult to understand if they are members of the extreme-spheroid population, unless the gas which formed the central regions of the spheroid was decoupled from the rest, but their spatial frequency and velocity dispersion are, in fact, compatible with their being disk stars.

The ratio of the mass of the second zone (thick plus thin disks), to the mass of the first zone (extreme spheroid) is approximately c/α , where α is the lock-up fraction in the first zone. Adopting a value of 0.8 for α , we then predict a present-day mass ratio, between the extreme spheroid and thick and thin disks together, of ~1:15. The thick- to thin-disk transition as modelled here predicts a further decomposition of masses to -1:3:12 for the ratios extreme spheroid:thick disk:thin disk. The later infall of primordial material, expected in most theories of galaxy formation and suggested by the thin disk metallicity distribution, will modify these ratios somewhat.

The global parameters of the Galaxy, which are required to estimate luminosities to compare with these predictions, are as

vet ill-determined. In particular, neither the radial scale-lengths nor axial ratios of any of the three major components of the Galaxy have been measured unambiguously. The most reliable technique available assumes that our Galaxy is extremely similar to other well-studied Sbc disk galaxies²³. This gives a decomposition of our Galaxy into extreme spheroid, thick disk and old thin disk²³, which implies a value of 1:11 for the ratio of the J-band luminosity of the extreme spheroid to that of the sum of the disks. Assuming similar mass-to-light ratios (~6), as for SO to Sbc galaxies in the B-band²⁴, yields good agreement with the value predicted above. The further decomposition into extreme spheroid:thick disk:old thin disk yields luminosity ratios 1:0.2:11, suggesting a less massive thick-disk component than predicted here. (Note that the young thin disk has negligible mass compared to the old thin disk.) However, these observational estimates for the thick disk are highly uncertain, being based in part on an extrapolation²³ of star counts in a single field to determine the global parameters. Indeed, Sandage¹⁰ finds the galactic thick disk to have a local normalization higher by a factor of $\sim 3-5$ than the earlier determination²³; this new value yields adequate agreement with the present model. By comparison, in NGC891, thought to be extremely similar to our Galaxy, the thick disk and extreme spheroid are of comparable mass²³. Even the r^{1/4} extreme-spheroid component in our Galaxy is poorly constrained by available data, two recent analyses differing by a factor of 3.45 in the luminosity of this component^{23,25}. Improved determinations of both the metallicity and spatial-structural parameters will only be available once the major statistical surveys underway by ourselves and others are completed.

The chronological sequence of formation of the three components proposed here may be tested by study of their detailed elemental and isotopic abundances²⁶. The transitions between components are likely to occur on timescales long compared with the lifetimes of the massive stars which explode as type II supernovae, but of the order of the lifetimes of the stars that produce carbon, nitrogen and type I supernovae. The available data on the variation of oxygen (from massive stars) and iron (from intermediate-mass stars) in stars over a range of metallicities spanning extreme-spheroid to thin-disk^{27,28} show a feature near $[Fe/H] \approx -1$, the transition metallicity between the extreme spheroid and thick disk. More exact location of this feature will allow us to estimate the duration of the formation of the extreme spheroid.

Although a full analysis of the chemical evolution of the Galaxy involves too many parameters for an analytical understanding, we believe that the simple model presented here offers new insight into the formation and evolution of the Galaxy. The galactic thick disk has a significant influence on the chemical evolution of the other components of the Milky Way.

We thank NATO for a travel grant (490/84) to aid collaborative research, the American Astronomical Society for grants (to R.F.G.W.) from the Small Research Grants Program, and Jim Truran for helpful comments.

Nimbus 7 satellite measurements of the springtime Antarctic ozone decrease

R. S. Stolarski, A. J. Krueger, M. R. Schoeberl, R. D. McPeters, P. A. Newman & J. C. Alpert*

NASA/Goddard Space Flight Center, Laboratory for Atmospheres, Greenbelt, Maryland 20771, USA

Farman et al. have reported a rapid decrease, since their measurements started in 1957, of the total column amount of ozone in late winter and early spring over the Halley Bay station in Antarctica (76° S, 27° W). The decrease was most pronounced in October, early spring in the Southern Hemisphere. They attributed the decrease to the increase in stratospheric chlorine due to chlorofluorocarbon release, and proposed that the unique conditions of extreme cold and low sunlight in the Antarctic winter and spring enhanced the effect. We report measurements from the Solar Backscatter Ultraviolet (SBUV) instrument and the Total Ozone Mapping Spectrometer (TOMS) aboard the Nimbus 7 satellite, a Sun-synchronous polar-orbiting satellite which passes any given point on the dayside near local noon. These provide global measurements of ozone from November 1978 to the present which confirm the reported decline of total ozone and show the phenomenon to be regional in extent. The decrease occurs during September as the Sun rises, reaching a minimum in mid-October. Seven years (1979-1985) of October monthly means show a 40% decrease in the ozone minimum and a 20% decrease in the surrounding ozone maximum.

The SBUV is a nadir-viewing instrument which obtains total ozone from measurements of the backscattered solar ultraviolet radiation in the wavelength range 310-340 nm (refs 2, 3). Measurements in the 250-310 nm range by the SBUV instrument provide information on the distribution of ozone with altitude. The TOMS instrument is designed to measure the spatial distribution of total ozone by scanning across the track of the satellite to obtain data between successive satellite orbital tracks. Both instruments make total ozone determinations using a differential absorption method which tends to cancel effects of neutral absorbers or scatters. Thus, stratospheric aerosol, such as polar stratospheric clouds (PSC), produce only second-order errors in retrievals. Errors due to wavelength-dependent scattering exist at large solar zenith angles⁴; however, PSCs are most common in winter, and vanish as the stratosphere warms in the spring^{5,6}, the time of the maximum decrease in ozone. Instrumental interference from PSCs, therefore, cannot account for the large observed ozone decrease.

One of the major advantages of the TOMS instrument is its ability to map total ozone over the entire globe on a daily basis. Figure 1 shows a daily sequence of total ozone observations for October 1984. The low total ozone over Halley Bay (indicated by an asterisk in Fig. 1) is part of a larger, elliptically shaped minimum region extending out to $\sim 60-70^{\circ}$ S. This region, which rotates about the pole with an irregular period of $\sim 7-10$ days, is bounded by a steep gradient where total ozone increases to values exceeding 300 Dobson units (1 DU = 10^{-3} atm cm). At $50-60^{\circ}$ S total ozone reaches a maximum, which exhibits larger variability due to travelling planetary waves. The polar minimum and mid-latitude maximum in total ozone are features of the normal, long-term climatology of the Southern Hemisphere⁷.

The 12 panels in Fig. 1 show 12 consecutive days, from 11 to 22 October 1984. This is the time period for which the lowest values are generally recorded. Each panel is centred about the South Pole and includes data out to 45° latitude. On 11 October, Fig. 1 shows that the minimum in total ozone is relatively symmetrical about the pole and the maximum in total ozone is

located in the lower right, between ~ 90 and 180° E. On succeeding days the total ozone maximum region rotates clockwise, while the minimum region elongates and begins to co-rotate with the maximum. On 16 and 17 October the maximum region has reached the lower left-hand corner, between 180 and 270° E, where it seems to dissipate and subsequently reappear in the upper right-hand corner. From there it continues to move around the pole but does not pass over Halley Bay. By 20 October the ozone distribution has returned approximately to the original situation on 11 October, giving a rotation period at this time of 9 days. The next 2 days are near repeats of 12 and 13 October.

Total ozone is proportional to the pressure-weighted integral of the ozone mixing ratio, and fluctuations in the amount of total ozone may indicate a relative increase in altitude of the mixing ratio distribution, a chemical loss in the lower stratosphere, advection of ozone into a region from other locations, or all of the above. Comparisons of National Meteorological Center (NMC) 50-mbar temperatures and TOMS total ozone reveals a high degree of spatial correlation on all of the days that have been examined. This correlation can be understood as resulting from the adiabatic ascent and descent of air as it moves around the vortex. Air which descends tends to increase total ozone while warming adiabatically. The reverse occurs when air ascends

The isobars at middle latitudes in the lower stratosphere are generally not parallel to the isotherms. As the isobars approximate the streamlines for air parcel motion, air parcels will experience large temperature excursions (20-30 K) as they circulate through the polar vortex. These excursions could play an important role in the chemistry of the air parcels and should not be neglected in model simulations. We have also noted that the streamlines pass through the edges of both the high and low total ozone regions. This suggests that the observed decrease in both the total ozone maxima and minima result from the year-to-year decrease in the mixing ratio of the group of parcels moving between the two regions. Thus, the total ozone maxima and minima decreases do not necessarily involve separate processes.

Evidence that the long-term total ozone decrease observed at Halley Bay is not unique to Halley Bay is shown in Table 1,

Table 1 Zonal mean, local minimum and local maximum total ozone values (DU) for October at 70-80° S latitude

Year	Zonal mean	Local minimum	Local maximum
1970	306	240	484
1971	334	249	482
1972	337	237	539
1979	333	235	515
1980	270	212	467
1981	266	206	422
1982	283	186	494
1983	245	166	479
1984	240	162	446

Data from Nimbus 4 BUV (1970-72) and Nimbus 7 SBUV (1979-84).

which lists the zonal mean, local minimum and local maximum total ozone values for 70-80° S latitude, for October 1970-72 from BUV and October 1979-84 from SBUV. Data from the Nimbus 4 BUV instrument, the predecessor to SBUV, were fairly complete for the 1970-72 period; in later years, coverage of the Antarctic by BUV was reduced. The BUV ozone data have been re-processed with the algorithm used for SBUV and with compatible instrument characterization functions, making it reasonable to compare the BUV total ozone with the SBUV total ozone. Antarctic total ozone in 1979 appears comparable to that observed in the early 1970s, indicating that most of the total ozone decrease has occurred since 1979, in agreement with the Halley Bay observations.

^{*} Present address NOAA/NMC, Camp Springs, Maryland 20233, USA.

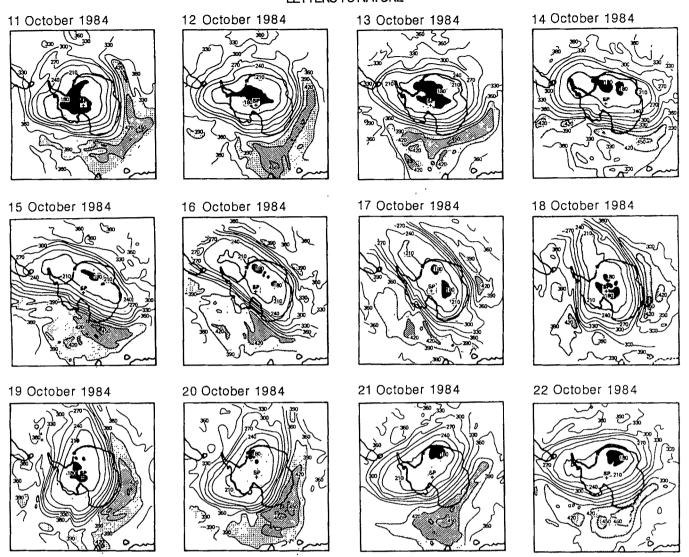

Fig. 1 Twelve-day sequence (11-22 October 1984) of TOMS measurements of total ozone content. The data are shown in south-polar projections, with the pole indicated by a cross (SP) and Halley Bay shown by an asterisk. Contours are every 30 Dobson units (1 DU = 10^{-3} atm cm). The region shown extends to ~45° latitude and the Greenwich meridian is towards the top of each diagram. Shaded regions indicate total ozone values <180 and 210 DU and >390 and 420 DU.

The nature of the decrease is shown more clearly in Fig. 2, which shows October monthly mean TOMS total ozone maps for the Southern Hemisphere in each of the seven years from 1979 to 1985. Table 2 lists the October monthly means over

Table 2 October mean ozone column over three Antarctic stations, along with the minimum and maximum values of the monthly mean (all in DU)

				•	
Year	Halley Bay (76° S, 27° W)	Syowa (69° S, 39° E)	Amundsen-Scott (90° S)	TOMS minimum	TOMS maximum
1979	273 ± 19	367 ± 47	266±25	259	458
1980	232 ± 11	276 ± 22	218±9	215	433
1981	244 ± 12	312 ± 30	223 ± 9	219	449

1984	190 ± 8	245 ± 24	187 ± 14	181	404
1985		•	•	152	351

Data from Nimbus 7 TOMS. Stated ranges are 1σ variances of the daily values from the monthly mean for each location.

three stations (Halley Bay, Syowa and Amundsen-Scott), as well as the minimum and maximum values of the monthly mean. The monthly mean values in the minimum region decrease from 259 DU in 1979 to 152 DU in 1985. The total ozone values for Halley Bay agree closely with those reported by Farman et al.¹.

We have also examined four years (1979-82) of NMC 50-mbar temperature data. The interannual variations in temperature were similar to the total ozone variations, but no conclusive trend could be determined from such a short data set.

The phase of the maximum in the October monthly mean total ozone at $\sim 60^{\circ}$ S latitude (Fig. 2) shifts from year to year, ranging from ~ 90 to 180° E. In 1979 the maximum monthly mean total ozone value exceeds 450 DU. By 1985 the maximum is barely > 350 DU, a decrease of > 20% in seven years. There also seems to be a biennial modulation of the decrease in both the maximum and minimum. A quasi-biennial oscillation in total ozone has been observed previously, but with a magnitude of only $\sim 6-8$ DU (refs 8, 9).

The data given by Farman et al.¹ for Halley Bay showed total ozone amounts at the end of the polar night in 1984 which were a few tens of per cent lower than those at the start of the polar night. The ozone algorithms for both TOMS and SBUV have been carefully scrutinized for their behaviour at high solar zenith angles and return accurate results for zenith angles up to 85° (ref. 3 and P. K. Bhartia, personal communication). We thus have observations back through the month of September for the latitude of Halley Bay (76° S). The results show values of total ozone as this region leaves polar night which are very close to those observed entering the polar night. This result is also in

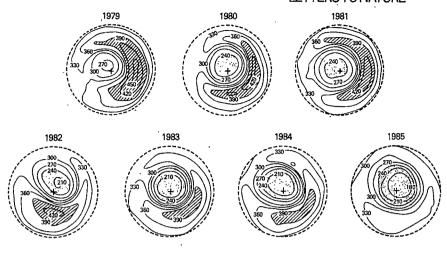

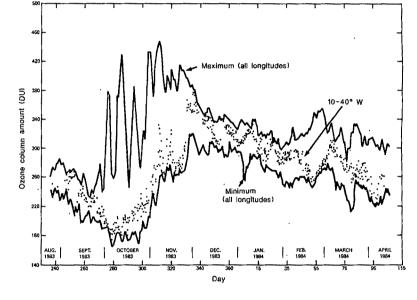

Fig. 2 Six-year sequence of October monthly means of total ozone. South polar projections, with the pole indicated by a cross and 30°S latitude by a dashed circle. The Greenwich meridian is towards the top of each panel. Contours are every 30 DU. The shaded regions indicate monthly mean total ozone amounts of <240 DU and >390 DU.

Fig. 3 Nimbus 7 SBUV data for total ozone content between latitudes 74°S and 78°S for September 1983 to April 1984. Dots, data within 15° longitude of Halley Bay (10-40° W). Solid lines, maximum and minimum values found around the entire latitude circle.

agreement with the observations of total ozone made at Syowa station (69° S) in 1982¹⁰. However, there is some indication from lunar Dobson and ozone-sonde measurements at Syowa that total ozone increases slowly until winter solstice, then decreases again until sunrise, with a more rapid decrease thereafter¹⁰.

Throughout the month of September and the first week in October, a rapid decline is observed in total ozone by both SBUV and TOMS, until the previously mentioned low values are obtained. Figure 3 shows this pattern in data from the SBUV instrument for late August 1983 to April 1984. The data points are the satellite data that are centred within $\pm 2^{\circ}$ latitude and $\pm 15^{\circ}$ longitude of Halley Bay. The solid lines are the maximum and minimum of values reported at all longitudes within the latitude band 74-78° S. Throughout October and November, the data over Halley Bay are consistently near the minimum values for all longitudes for this and other years. The decline in the minimum value of ozone column extends from late August to early October at a rate of ~0.6% per day. At longitudes on the other side of the pole from Halley Bay (near the total ozone maximum), the total ozone amount is more variable.

Near the end of November the low values have disappeared completely and the minimum curve attains its largest values. The jump in total ozone occurs several weeks after the final warming in the Southern Hemisphere, and marks the switch from winter to summer circulation. A similar process occurs in the Northern Hemisphere, but usually only three months after the winter solstice rather than five months, as seen here^{11,12}. Throughout the Antarctic summer the ozone column decreases again, and the Halley Bay values oscillate between the maximum

and minimum curves as lower stratospheric travelling waves pass over the station.

Our data place significant constraints on possible mechanisms for explaining the decrease. The deep minimum, or hole, follows the polar vortex, and its position is well correlated with the temperature minimum in the lower stratosphere. There also appears to be a smaller but significant decrease (~20%) in the total ozone maximum surrounding the polar region over the seven years studied. The decrease in the total ozone maximum is related to the decrease in the total ozone minimum, in that the streamlines indicate that air in the maximum region has passed through the periphery of the low-temperature region which is associated with the total ozone minimum.

An important constraint placed on theoretical models by these data is that the decrease in total ozone near the pole appears to take place largely in September, during twilight, not in the polar night. The maximum rate of decrease in total ozone occurs after most of the polar region is sunlit, and in 1983 was $\sim 0.6\%$ per day, extended over 40-50 days.

Any explanation of the total ozone change must be consistent with the year-to-year changes in the polar vortex, as well as with the rate of decrease through September. Various ideas have been proposed, involving combinations of chlorine chemistry, heterogeneous chemistry taking place in polar stratospheric clouds, bromine chemistry and dynamical elevation of the polar stratosphere^{1,13-15}.

We estimate that in order for chlorine chemistry at 1983 concentrations to cause the 0.6% per day decline in September, virtually all of the chlorine must be in its active state, that is,

Cl and ClO, with little or no interference from NO_x. Therefore, any proposed chlorine mechanism must be able to remove most of the chlorine from both the HCl and ClONO2 reservoirs and to tie up NO_{xx} probably as HNO₃. Such a mechanism could involve the cold temperatures and/or polar stratospheric clouds that form within the polar vortex⁶.

Any conclusions concerning the implications of the observed Antarctic decreases in total ozone for predictions of the effects of chlorine from chlorofluorocarbons must await a proven mechanism and continued observations to verify the persistence of the phenomenon. Only then will we be able to evaluate clearly the relative roles of chemistry, radiation and dynamics in contributing to the observed decrease.

We thank the Nimbus 7 ozone processing team (A. Fleig, chairman) for making available TOMS data from October 1983, 1984 and 1985; the Real-Time TOMS Project for data for a few days in October of 1985 before regularly scheduled processing; Reggie Galimore for image processing which helped make the data readily available for visual examination; S. Solomon, S. Wofsy and N. D. Sze for discussing and making available preprints of their papers: S. Chandra for useful discussions: and Lori Winter and Roberta Duffy for typing the many versions of this manuscript.

Are Antarctic ozone variations a manifestation of dynamics or chemistry?

Ka-Kit Tung*, Malcolm K. W. Ko†, José M. Rodriguez† & Nien Dak Sze†

* Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, and Clarkson University, Potsdam, New York 13767, USA

† Atmospheric and Environmental Research, Inc., Cambridge, Massachusetts 02139, USA

Observations¹⁻³ reveal a large seasonal decrease in the column density of ozone during Antarctic early spring, followed by a rapid increase after October beyond its pre-spring value. Given the unique circumstances that exist in the Antarctic environmentrelatively stable circumpolar vortex, cold air temperature achieved during polar night, and the increase in absorption of solar radiation by ozone as the Sun returns—we surmise the existence of a reverse circulation cell with rising motion in the polar lower stratosphere. The upwelling brings ozone-poor air from below 100 mbar to the stratosphere, possibly contributing to the observed ozone decline in early spring. At the same time, the Antarctic stratosphere might contain a very low concentration (<0.1 p.p.b.v. (parts per 10⁹ by volume) of NO_x(NO+NO₂), a condition that could favour a greatly enhanced catalytic removal of O₃ by halogen species^{2,4,5}.

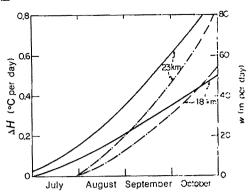

Fig. 1 Calculated heating rate (ΔH) from O₃ absorption over a 24-h period, as a function of time, for 69° S (--) and 76° S (- · - · -) at different altitudes. The heating rates are calculated from the local O₃ concentration using the parameterization of Strobel³¹. The time variation mainly reflects the seasonal changes in the number of sunlit hours. The observed O₃ profile from Syowa Station in July is adopted as the initial condition. For this calculation, horizontal transport and photochemical removal are ignored. The O3 profile is updated in time by accounting for the effect of the upward advection w by equation (4). The right-hand scale indicates the approximate value of \vec{w} , assuming that $\Gamma = 10 \,^{\circ}\text{C km}^{-1}$.

We argue that heterogeneous processes and formation of OCIO by the reaction BrO + ClO → OClO + Br before and after the polar night might help to suppress the NO_x levels during the early spring period. However, the dilution of the concentrations of the chlorine species by the upwelling may reduce the effectiveness of the photochemical removal of O3.

The zonal mean transport in the lower stratosphere normally takes the form of a two-cell diabatic circulation, with rising motion in the tropics and subsidence near both poles⁶⁻¹⁰. For a species such as O₃, whose source is in the stratosphere, upward transport tends to reduce its column abundance, as tropospheric air with low O₃ mixing ratio is brought up to the stratosphere. Poleward and downward transport in the subsiding branches tends to increase its abundance at high latitudes. This situation is further accentuated in winter by the downward branch of the one-cell circulation that exists above 25 km (refs 11, 12). The latitudinal distribution of the column abundance of O₃ does not, however, have north-south symmetry 13,14, as the spring maximum in the Southern Hemisphere is located closer to the Equator than in the north.

The winter polar vortex that encircles Antarctica is less disturbed than its counterpart in the Northern Hemisphere because of the weaker stationary planetary wave perturbations forced by large-scale continental elevations and land-sea contrasts. Although the vortex may shift in position and deform in shape in response to wave perturbations, its integrity (as defined in ref. 15) is usually maintained until its breakdown in early November. It therefore appears that irreversible wave-induced transports16 do not effectively reach Antarctica during this period.

During the polar winter in the Southern Hemisphere, dynamical transport of heat into the circumpolar vortex is weak. Local temperatures in the Antarctic lower stratosphere have time to adjust so that cooling, C(T), approximately balances diabatic heating, H, to reach low values 17, approaching the radiative equilibrium temperature T_e (refs 18, 19), with $H - C(T_e) = 0$. The situation changes abruptly when the Sun returns. Absorption of solar radiation by O3 causes H to increase rapidly as the number of sunlit hours increases. However, radiative cooling to space, which is temperature-sensitive, remains close to the low value achieved during the polar night. The temperature evolution is constrained by the prognostic zonal momentum and energy equations through the thermal wind relationship and mass continuity equation. Thus, local temperature can adjust

only on a longer dynamical timescale, due to 'dynamical inertia' ^{18,20}. In the absence of wave transports, the dynamical timescale is found²⁰ to be related to the newtonian cooling timescale of about 1-2 months for the Antarctic lower stratosphere²¹. The radiative imbalance temporarily leads to a positive net heating,

$$O = H - C \approx \Delta H > 0 \tag{1}$$

where ΔH is the incremental increase in heating due to absorption of solar radiation.

The above increase in net heating may be balanced by an increase in local air temperature (T), or by a vertical ascent of the heated air mass or both. This follows from the zonal-mean thermodynamics equation, which is, neglecting wave transports,

$$\bar{Q} = \frac{\partial}{\partial t} \, \bar{T} + \Gamma \bar{w} \tag{2}$$

where $\Gamma = (\partial \bar{T}/\partial z) + 9.8$ °C km⁻¹ is the static stability parameter, the overbar denotes the zonal mean and \bar{w} is the residual mean vertical velocity. Because of the 'dynamical inertia', the net heating should lead mainly to an upward circulation with vertical velocity

$$\bar{w} \simeq \bar{Q}/\Gamma$$
 (3)

during early spring. The upward branch of this reverse circulation in the lower stratosphere occurs in the vortex where $\bar{T} < T_c$, while the downward branch occurs at the edge of the polar vortex where $\bar{T} > T_c$. As upwelling (subsidence) lowers (raises) the column density of O_3 , it follows from the above arguments that, during the Antarctic spring, cold (warm) temperature should be correlated with O_3 minimum (maximum) at the altitude where O_3 concentration is largest. This is consistent with observation³. In the northern polar stratosphere, winter temperatures are maintained by dynamical transport, leading to values ~20-30 °C warmer than the temperature that prevails over the southern winter pole. Radiative cooling thus tends to exceed heating in Arctic winter, resulting in a downward diabatic circulation, as evidenced by the movement of stratospheric aerosols²².

To estimate the effect of upwelling on O_3 , we use a simple model based on the zonal-mean equation for the O_3 mixing ratio \bar{f} ,

$$\frac{\partial \vec{f}}{\partial t} + \vec{v} \frac{\partial \vec{f}}{\partial y} + \vec{w} \frac{\partial \vec{f}}{\partial z} = 0 \tag{4}$$

where the effect of irreversible mixing and photochemical reactions are neglected. As the residual mean meridional velocity (\bar{v}) is small near the pole, the effect of horizontal transport is also neglected. Figure 1 shows the calculated heating rate, ΔH , due to the absorption of solar radiation by ozone alone. The vertical advective velocity is calculated using equations (3) and (1), as described in Fig. 1 legend. Figure 2a, b shows a comparison of our calculated column densities of O_3 with observations at Syowa Station for 1982 (ref. 1) and with those at the latitude of Halley Bay for 1983 (ref. 3). The calculated rate of decline in September and October appears to be consistent with the observed zonal mean values³, but is smaller than the minimum over all longitudes.

An assessment of the photochemical contribution is hampered by the lack of kinetic data. The following discussion should be viewed as an assessment of the requirements on photochemistry for it to explain the observed O₃ behaviour. McElroy et al.⁴ have proposed that catalysis of O₃ recombination involving the bromine-chlorine cycle²³ may be important in Antarctic early spring:

$$Br + O_3 \rightarrow BrO + O_2$$

$$Cl + O_3 \rightarrow ClO + O$$

$$ClO + BrO \rightarrow Cl + Br + O_2$$

$$2O_3 \rightarrow 3O_2$$
(5)

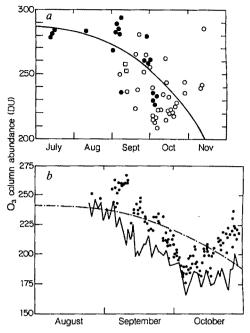

Fig. 2 a, Calculated column abundance (in Dobson units; 1 DU = 10^{-3} atm cm) of O_3 at 69° S (curve), compared with observations for the Syowa Station¹. The O_3 profile is calculated as described in Fig. 1 legend. The O_3 advected out of the top of the vortex (at ~ 30 km) is assumed to be swept away by horizontal motion and will not contribute to the column content. The data are from Dobson instrument by direct Sun (\bigcirc), by cloudy zenith (\square) and by Moon (\bigcirc). b, Calculated column abundance of O_3 at 76° S ($-\cdot-\cdot$) compared with observations from the Total Ozone Mapping Spectrometer (TOMS)³. The computation procedure is as stated in a, except that solar insolation is calculated for 76° S and the initial O_3 profile is adjusted to give an initial value of 240 DU for the column content. The data from TOMS³ comprise the minimum observed values for all longitudes between 74° S and 78° S (solid line) and observations at Halley Bay (dots).

In order for reaction (5) to provide a decrease of 0.5% per day in the column abundance of O_3 , the 24-h-averaged abundances of ClO and BrO at ~18 km must be ~0.4 p.p.b.v. and 20 p.p.t.v. (parts per 10^{12} by volume), respectively.

Results of our two-dimensional model¹¹ indicate a total chlorine (ClY) mixing ratio of 2.6 p.p.b.v. in the upper stratosphere and 1.5 p.p.b.v. at 18 km, of which 30% is in the form of ClO_x (ClNO₃+Cl+ClO+OClO+2×Cl₂+HOCl). If the observed decrease in O₃ were to be explained by photochemistry alone, ClO would have to be the major ClO_x species in early spring. The daytime abundances of the species Cl, ClO and CINO₃ are primarily determined by the equilibrium between production of ClO by photolysis of ClNO3 and rapid re-formation of CINO3, with equilibrium achieved within 1-2 h of daylight²⁴. To maintain the high ClO concentration, we must consider processes which both convert ClNO₃ to ClO_v (Cl+ClO+ OCIO+2×Cl₂+HOCl) and maintain sufficiently low NO_x to inhibit re-formation of ClNO₃. It is also important to consider the initial conditions of chlorine and nitrogen species in late autumn when the polar vortex is established before entering polar night.

Figure 3 summarizes the possible chemical mechanisms controlling chlorine and nitrogen species from Antarctic late autumn to early spring. Net conversion of NO_x to N_2O_5 occurs in the late autumn due to the rapidly decreasing photolysis rates of N_2O_5 with increasing solar zenith angles and shorter days. As the NO_x decreases, the daytime ClO increases, until the ClO and NO_x concentrations are comparable. From that point on, all ClO and NO_x will be sequestered in ClNO₃ within 1-2 h of darkness. Under these conditions, we calculate daytime concentrations of ClO of 0.07 p.p.b.v. at 18 km during late autumn

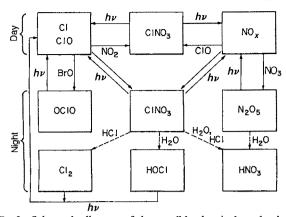

Fig. 3 Schematic diagram of the possible chemical mechanisms controlling nitrogen and chlorine species from late autumn to early spring in Antarctica. Species in the upper ('day') and lower ('night') portions are formed primarily during the day and night, respectively. Dashed lines: reactions proceeding through both homo- and heterogeneous channels. We note that although HOCl and HNO3 are produced primarily during the day for mid-latitude conditions, such production is negligible for high-latitude late autumn to early spring, due to the low abundances of OH and HO2.

and early spring, corresponding to a 24-h-averaged ClO of 0.02 p.p.b.v.

Further net conversion of NO_x to N₂O₅ is possible only if there is another night-time sink for ClO to prevent formation of CINO₃. Bromine chemistry may provide such a mechanism through the reaction²⁵

$$BrO+ClO \rightarrow Br+OClO$$
 (6)

The measured rate constant²⁵ implies a ClO time constant of 1 h for a BrO mixing ratio of 20 p.p.t.v. Conversion of ClO to OCIO by reaction (6) will dominate over CINO3 formation if the abundance of NO_x is <0.1 p.p.b.v., again facilitating the conversion of NO₂ to N₂O₅ at night and correspondingly increasing the equilibrium concentration of ClO during the day by a factor of 3. Reaction (6) effectively removes all ClO at night, restricting the effect of reaction (5) to daytime only.

Photolysis of N₂O₅ would constitute an important source of NO_x within 1 week after emergence from polar night, thus re-forming ClNO₃ at the expense of ClO. Concentrations of N₂O₅ may be kept low by assuming the heterogeneous reaction²⁶

$$N_2O_5 + H_2O (aerosol) \rightarrow 2 HNO_3$$
 (7)

with an equivalent first-order rate of $10^{-6}\,\mathrm{s}^{-1}$ near 18 km. This rate implies values of 10^{-2} for γ , the probability of reaction per collision with an aerosol surface, if we assume the background aerosol concentrations of ref. 27. The required value of γ could be reduced by more than a factor of 10 if we adopt the enhanced aerosol abundances for periods of high volcanic activity or the existence of polar stratospheric clouds²⁸.

Other heterogeneous processes have been proposed to convert CINO₃ to CIO_y and maintain low NO_x concentration. We find that the reactions^{4,5,32}

$$CINO_3 + H_2O (aerosol) \rightarrow HOCl + HNO_3$$
 (8)

$$ClNO_3 + HCl (aerosol) \rightarrow Cl_2 + HNO_3$$
 (9)

could achieve substantial conversion of ClNO₃ if an equivalent first-order rate of 10⁻⁶ s⁻¹ is assumed, leading to daytime ClO abundances in August of 0.5 p.p.b.v. and 1 p.p.b.v. with reactions (8) and (9), respectively. Higher rates are needed if reactions (8) and (9) are to counteract the production of NO_x by photolysis of HNO₃ a month after emergence from polar night⁴. In our proposed model upwelling may become important at this time, lowering the concentrations of ClY as well as O3, and reducing the importance of photochemistry. The extent of photochemical depletion during the first month will, however help determine

the magnitude of the subsequent October minimum and possibly contribute to the interannual trend.

The above discussion pertains to seasonal variations of Antarctic ozone and does not address the observed interannual trend of decreasing October minimum values since 1979 (refs 2, 3) While theories based on chemistry mostly attribute the secular trend to increases in stratospheric chlorine^{2,4,5}, enhanced upwelling over recent years may also play a part. Aerosol loading of the Antarctic stratosphere has increased by almost an order of magnitude in recent years²⁹, due probably to a series of major volcanic eruptions since 1979. Absorption of solar radiation by aerosol particles³⁰ would increase ΔH . During the polar night, increased cooling in the 10-50 mbar region from the higher aerosol loading could lead to a more negative vertical temperature gradient and a smaller Γ . Equation (3) then implies a stronger upwelling when the Sun returns. Our present calculation does not incorporate these additional factors and presents only a baseline model for a 'clean' atmosphere, designed to demonstrate the seasonal trend.

The proposed mechanisms (dynamical and chemical) have different implications for the susceptibility of stratospheric O₃ to atmospheric perturbations, and may manifest themselves in different ways and at different times in spring. The chemical mechanism may be dominant during the initial decline after the return of the Sun, when the strength of upwelling is still weak. Thereafter, however, the CIY concentrations may be reduced by the upwelling, effectively diminishing the catalytic removal of O₃. Future measurements should be aimed at evaluating the relative importance of the two separate processes.

The radiative-dynamical mechanism we have described should be reflected in the temporal and spatial behaviour of many long-lived species and stratospheric aerosol. As a result of the existence of the reverse circulation, we may expect to see increasing abundances of 'upward-diffusing' species (such as chloro-fluorocarbons, N2O and CH4) and decreasing concentrations of 'downward-diffusing' species (HNO3, HCl, stratospheric aerosol) during early spring in the Antarctic lower stratosphere. Simultaneous observations of these trace gases and aerosols will be useful. Observations of the vertical temperature gradient will determine values for Γ , providing better estimates of \bar{w} from ΔH .

The chemical mechanisms require concentrations of ~0.5-1 p.p.b.v. for CIO and 20 p.p.t.v. for BrO. Levels of OCIO comparable to those of daytime ClO could be obtained at night starting in late autumn, if sufficient BrO is present. The OClO is photolysed within minutes after sunrise, with a correspondingly rapid increase in ClO. Observations of the diurnal variation of both ClO and OClO will yield indirect evidence of the magnitude of the BrO abundance. Measurements of NO2 in the lower stratosphere are also needed. The technology for measuring these species is presently available and should be used.

This research has been supported by NASA grants NAGW-798 to MIT and NAGW-4080 to AER. K.-K.T. acknowledges support from the John Simon Guggenheim Foundation during his sabbatical year. Work at AER is also supported by the Fluorocarbon Program Panel of the Chemical Manufacturers Association. We thank M. McIntyre, M. Prather and A. Tuck for comments, S. Chubachi for reprints, and M. McElroy, S. Solomon and R. Stolarski for providing us with their results before publication.

High-resolution lattice imaging reveals a 'phase transition' in Cu/NiPd multilayers

C. S. Baxter & W. M. Stobbs

Department of Metallurgy and Materials Science, University of Cambridge, Pembroke Street, Cambridge CB2 3QZ, UK

Considerable interest has been generated in metal multilayers by the discovery of anomalous variations in their physical properties as a function of layer thickness. Of particular interest is the 'supermodulus effect', observed for several multilayer systems at modulation wavelengths of 1.6-3.0 nm, in which an elastic modulus can increase by up to 400% (ref. 1). Various explanations for this effect have been suggested, and as part of an investigation aimed at clarifying the role of coherency strains in multilayer properties we are studying the behaviour of Cu/NiPd multilayers. We have developed transmission electron microscopy (TEM) techniques which allow the structural characterization of these materials, including the measurement of both the extent of interlayer mixing and the lattice plane spacings. Here we present some of our results in the latter category and discuss data which indicate that a novel form of 'phase transition' occurs as the modulation wavelength is decreased.

Metal multilayers typically consist of ~1,000 alternating layers of two metals or alloys, with modulation wavelengths (defined as the combined thickness of adjacent layers of each material) in the range 1.0-6.0 nm. Explanations which have been put forward for wavelength-dependent multilayer property changes range from theories based on critical Fermi surface/Brillouin zone interactions to arguments that consider the consequences of interlayer stress relaxation by the generation of misfit dislocations. The development of Fermi surface theories is hindered by the fact that the precise form of multilayer Fermi surfaces is not known, but as a first approximation these can be taken as equivalent to those of the corresponding homogeneous alloys. For example, it has been shown² that the peaks in modulus of both Ag/Pd and Cu/Ni multilayers occur at modulation wavelengths for which the additional Brillouin zones introduced by the modulations make tangential contact with the alloy Fermi surfaces. Any theoretical approach necessitates the selection of appropriate structural models to represent the multilayers, so we have had to develop new TEM techniques allowing better structural characterization of a multilayer than is possible by X-ray methods. The Cu/NiPd multilayer system has the added advantage in this context that the difference

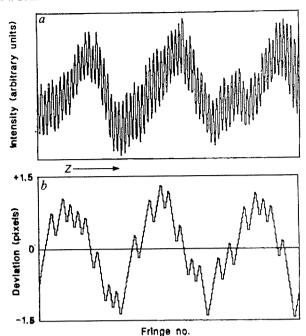

Non-axial lattice image of a Cu/NiPd multilayer taken on the Cambridge HREM operated at 500 kV. Scale bar, 2 nm.

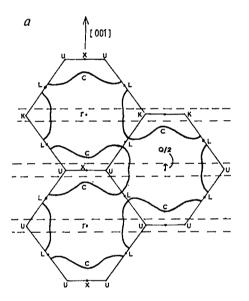

between the bulk lattice parameters of the layers (and hence the resulting coherency strains) can be altered systematically by varying the Ni: Pd ratio. Our observations indicate that interfacial dislocations do not play a critical role in the behaviour of the Cu/NiPd system at or near critical wavelengths, and this result is discussed elsewhere³.

The multilayers we have used were deposited by Somekh using a magnetron sputter deposition system⁴. Although we have examined films grown with both [001] and [111] epitaxial orientations, the results we report here are for [001]-oriented films only.

A fundamental part of our structural studies has been an attempt to locate the atomic positions as accurately as possible using high-resolution electron microscopy (HREM). Obtaining analysable high-resolution images of a modulated structure, even when thin enough to be treated as a weak-phase object, requires better resolution than is needed for the measurement of lattice spacings in either layer alone. This is because the modulated spacing variations are associated primarily with the high-frequency Fourier coefficients. Simulations for idealized specimens (that is, those exhibiting no variations in phase caused by, for example, local thickness changes) indicate that the lattice plane spacing variations should be detectable in axial lattice images, although the fringe positions would be too sensitive a function of defocus to be analysed reliably. In fact, despite sufficient resolution for accurate imaging of the spacings concerned in uniform specimens, in practice the variation cannot be detected⁵—presumably because when working near the limit of the transfer function the sensitivity of the image to inevitable local phase changes is accentuated. We have overcome this problem by using non-axial rather than axial illumination conditions, which increases the accuracy to which lattice spacings can be measured⁶; a typical image of a 4.4-nm modulationwavelength Cu/NiPd multilayer is shown in Fig. 1. Images of this type now contain modulated fringe spacings, as revealed by the measurements shown in Fig. 2b, obtained from the fringe intensity profile shown in Fig. 2a. Our analysis of these profiles has allowed us to determine the lattice strains of multilayers with relatively large modulation wavelengths and lattice mismatch⁷, but for specimens for which either the lattice mismatch is small or, more frustratingly, the wavelength is low (including the anomalous range near 2.0 nm), the modulation cannot be detected above the random noise in the fringe measurements. However, in these cases it is still possible to gain significant structural information by measuring the average lattice spacings in directions parallel and perpendicular to the layer normal $(\bar{d}(002))$ and $\bar{d}(020)$ respectively). The lattice mismatch between the layers in our multilayers is accommodated by coherency strains, and conventional elasticity theory can be used as a first approximation to predict the expected values of these average spacings, which will not generally be the same. The relative values of $\bar{d}(002)$ and $\bar{d}(020)$ can be measured from lattice images with a high degree of accuracy ($\sim \pm 0.2\%$), and when this is done for a relatively long-wavelength (4.4 nm) Cu/NiPd multilayer we find that the measured difference in the two spacings has the same sense and size $(\bar{d}(020) \ 1\%$ bigger than $\bar{d}(002))$ as

Fig. 2 a, Intensity profile of lattice fringes from a Cu/NiPd multilayer as used for measuring fringe positions. b, Deviations from line of least-squares fit of fringe positions measured from a; the mean fringe spacing is 6.6 pixels. To show the modulation clearly, these data have been presented as the deviation of each successive fringe position from the line of least-squares fit through the fringe positions: in this format, the maximum spacing is associated with the maximum positive gradient and the minimum spacing with the maximum negative gradient. As with any high-resolution imaging, care is needed in the interpretation of these measurements and the measured fringe spacings cannot be directly related to the lattice spacings in the multilayer. Instead, the spacings measured from a focal series of images were compared with spacings in images simulated using multilayer models with different interlayer strains. These models were based on composition profiles determined by a Fresnel method^{5,7}. For the image series including the example shown in Fig. 2, the best match between the simulated and measured spacing variations (9% in Fig. 2b) was found for a model with a 6% variation in lattice plane spacing. The fit with a value of 6% is less than would have been expected for a nominal misfit of 3.5% (as for Cu/Ni_{0.5}Pd_{0.5}), but the reduced value is presumably explained by surface relaxation in the TEM specimen⁸.

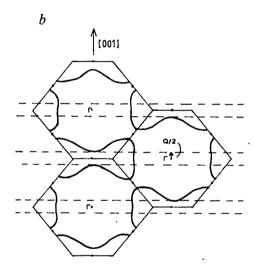

Fig. 3 a, Possible Fermi surface of Cu/NiPd drawn in the periodic zone scheme (based on Fermi surface of CuNi (ref. 9) and with I, X, L, K and U used conventionally to indicate high-symmetry points of the Brillouin zone). The zone boundary introduced by a 1.6-nm wavelength modulation along [001] (wave-vector (1) are also shown. No points of tangential contact occur, but contact could occur at C with a shorterwavelength modulation, b, Possible Fermi surface of Cu/NiPd with a tetragonal distortion of the unit cell such that the mean (002) lattice spacing is increased by 10%. The zone boundaries corresponding to the 1.6-nm modulation now make contact with the Fermi surface.

predicted by our linear elasticity calculations. However, at the shorter wavelength of 1.6 nm, $\tilde{d}(002)$ is 2.5% greater than d(020), and this cannot be accounted for using conventional elasticity theory. We are convinced that this result reflects a genuine wavelength-dependent change in the structure of the specimens rather than an electron-optical imaging artefact, because both differences were found to be consistently measureable to an accuracy far greater than the random errors involved for a range of specimen thickness, objective defocus and illumination conditions. Furthermore, surface relaxations, although undoubtedly important⁸, could not provide an explanation for this phenomenon: such effects are most marked when the specimen thickness is comparable to the wavelength, but the anomalous spacings are found in short-wavelength multilayers where the specimen thickness is at least 10 times the wavelength. We therefore conclude that an anomalous change has occurred in the structure of the shorter-wavelength multilayer, which can be thought of as a transformation to a novel tetragonal 'phase'. The transformation is difficult to model because of uncertainties in the electronic structure, but a consistent qualitative interpretation can be obtained by examining the consequences of the observed structural distortion on possible Fermi surface/Brillouin zone interactions. As a starting point, we have taken the Fermi surface of a Cu/NiPd multilayer as being approximately equivalent to that of a homogeneous CuNi alloy: this is shown in Fig. 3a for an undistorted cubic unit cell, together with the Brillouin zone introduced by a 1.6-nm modulation along [001]. No points of critical contact occur at this wavelength, but contact would occur at the points marked 'C' for shorter-wavelength (longer-wave-vector) modulations. However, critical contact is obtained at a wavelength of 1.6 nm if a tetragonal distortion of the crystal structure is introduced such that the dimensions of the Fermi surface remain approximately constant with respect to the origin but the lattice dimension along [001] is increased by $\sim 10\%$ (see Fig. 3b). The distortion required for contact is more than twice the observed change in the mean spacings (~4%), but both the substitution of Pd for Ni and the presence of the lower band gaps introduced by the modulation will raise the Fermi energy, while the Fermi surface would be expected to be increasingly distorted towards the Brillouin zone boundary as the modulation wavelength is decreased towards the value at which critical contact can occur by a 'transformation' of structure. This argument is clearly grossly oversimplified and a full calculation of any accuracy would be very difficult, but it is apparent that the trends indicated are in the observed direction.

This picture has several consequences: for example, while the transformation would be first-order thermodynamically, given

the associated changes in volume, precursory effects would be expected which should be reflected in progressive changes in physical properties on either side of the critical wavelength (as are, in fact, generally observed). A transformation-induced mechanism for the changes in physical properties of otherwise isostructural metal multilayers could thus have general significance. It is not clear whether the transformation we have observed occurs in one or both components of the multilayer, but it might be possible to design a system for which both layers exhibit transformations at different wavelengths. Any correlated anomalies in the physical properties, if observed, would be useful in testing the ideas outlined.

Whatever the precise mechanism for the 'transformation', our data demonstrate a fundamental change in the structure of Cu/NiPd multilayers as a function of the modulation wavelength. Experiments are in hand to correlate the wavelength dependence of the structural and physical anomalies of this system.

The determination of osmium content and isotopic abundances in geological materials has received increasing attention in recent years following the proposal of Alvarez et al. 1 that mass extinctions at the end of the Cretaceous period were caused by the impact of a large (~10 km) meteorite which left anomalously high iridium levels as a geochemical signature in the boundary shales. Here we report a new and simple method for measuring osmium in geological materials, involving fusion of the sample with sodium peroxide, distillation of the osmium as the tetroxide using perchloric acid, extraction into chloroform, and absorption of the chloroform extract onto graphite powder before instrumental neutron activation analysis. In a variant of this technique, the chloroform extract is back-extracted into an aqueous phase and the osmium isotopes are determined by plasma-source mass spectrometry (ICPMS). We have used this method on the Woodside Creek (New Zealand) Cretaceous/Tertiary boundary clay and have obtained the first osmium content (60 ng g^{-1}) for this material. The $^{187}Os/^{186}Os$ ratio is 1.12 ± 0.16 , showing a typical non-crustal signature. This combined distillation-extraction-ICPMS method will prove to be useful for measuring osmium isotopes in other geological materials.

Although ~50 Cretaceous/Tertiary (K/T) boundary sites with anomalous iridium levels have now been discovered2, only one of these, at Woodside Creek, New Zealand, is on land in the Southern Hemisphere and is therefore of some importance for an interpretation of the events which occurred at the end of the Cretaceous. The geochemistry of the Woodside Creek occurrence has been reported by Brooks et al.3, who found 153 ng g⁻¹ iridium (carbonate-free basis) in the basal layer of the 8-mmthick boundary shale, together with an integrated iridium deposition of 187 ng cm⁻²

Most of the original work on the K/T boundary in different parts of the world involved the use of iridium as a marker. particularly as this element is easier to determine by neutron activation analysis (NAA) than are the other platinum metals. Osmium, which has a similar abundance to iridium, serves almost equally well as an indicator of extraterrestrial (or mantle) material, but has a sensitivity ~30 times poorer than that of iridium when determined by neutron activation. The isotopic ratio 187Os/186Os is also of use in explaining the nature of geochemical signatures, as meteorites (and mantle material) typically have ratios near 1.0 (ref. 4), whereas crustal material averages ~ 10.0 (refs 5, 6).

The recent development of ICPMS for determining isotopic abundances⁷ has opened up exciting new possibilities for determining these isotopes in geological materials. We have therefore developed a technique of removing osmium from rocks by distillation, followed by ICPMS or instrumental NAA (INAA) determinations. This procedure has been applied to the measurement of osmium isotopes in the Woodside Creek K/T boundary shale, as described below.

Samples of the basal 2-mm layer of the boundary shale (0.5 g) were fused with 5 g of sodium peroxide at 650 °C for 2 min. After cooling, the melt was transferred to a 50-ml flask together with 20 ml of 70% perchloric acid, and distillation was carried out into a receiver initially containing 2 ml of the same acid. After 8 ml of mixture had been recovered, distillation was terminated and the distillate was shaken for 5 min with 10 ml of chloroform. The extract was used either for INAA or for ICPMS determinations. For the former purpose the extract was mixed with 10 ml of a 1:1 chloroform/ethanol reagent containing 0.5% thiourea acidified with perchloric acid (2% v/v), and the combined mixture was absorbed and evaporated drop by drop on 1 g of high-purity graphite powder. The powder was analysed for osmium by INAA using a Slowpoke reactor with a flux of 5×10^{11} n cm⁻² s⁻¹. The irradiation time was 16 h and counting was performed for 16 h or longer using a Ge(Li) detector or LEPD (low-energy particle detector) after a decay period of 7

For the ICPMS determinations the chloroform extract was back-extracted into 2 ml of an aqueous phase containing 1% thiourea and 0.5 M sulphuric acid. The spectrometer was a Sciex Elan ICP-MS instrument with a glass frit nebulizer⁸ which

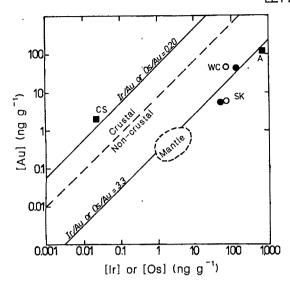

Fig. 1 Plots of gold versus iridium (•) or osmium (O) in crustal, meteoritic and K/T boundary material (, both Ir and Os). CS, mean for Canadian Shield⁷; SK, Stevns Klint⁸; WC, Woodside Creek (this work); A, Allende carbonaceous chondrite (this work).

increased nebulization efficiency to 90%, compared with 1-3% for conventional nebulizers. Each sample was analysed 10 times with a total integration time of 15 min at a nebulization rate of 30 μ l min⁻¹. Standard deviations (2 σ) were calculated automatically by the on-board computer. Other instrumental conditions were: r.f. power 1,150 W, nebulizer gas flow rate 0.7 litre min⁻¹, plasma gas 13 litre min⁻¹, sheath gas 1.0 litre min⁻¹, plasma sampling distance 22 mm from the load coil. The instrument was calibrated using an osmium standard dissolved in thiourea and sulphuric acid to match the sample solutions. The normalized instrument response was verified against the Allende meteorite standard, which has documented isotopic abundances. A reagent blank showed no detectable blank for any osmium

Table 1 lists the data for total iridium and osmium and for the ¹⁸⁷Os/¹⁸⁶Os isotopic ratios. The osmium data are the first reported for the New Zealand material. Our data for the Allende carbonaceous chondrite and other data for K/T boundary material from Stevns Klint, Denmark, are also given.

Experiments with samples spiked with known amounts of osmium indicated a recovery of 93% in the distillation-extraction procedure. After allowing for this factor, we obtain a total osmium content of 720 ng g⁻¹ (by INAA) for the Allende specimen, which is close to the values of 745 ng g⁻¹ (ref. 9) and 828 ng g⁻¹ (ref. 10) reported by other workers. Our value of 60 ng g⁻¹ for osmium in the Woodside Creek basal layer is identical to that found by Kyte et al. 11 for Stevns Klint, and is in line with the observation of Brooks et al.3 that the New Zealand and Danish K/T shales have similar chemical compositions (apart from the higher CaCO₃ content of the latter).

Palme et al. 12 have pointed out that the Ir/Au ratio in geological materials is a reliable geochemical signature by which to separate crustal and non-crustal samples. As the osmium and iridium concentrations in chondrites are almost identical (~700 ng g⁻¹), the Os/Au ratio should be an equally reliable marker for non-crustal materials. Figure 1 shows a plot of gold versus iridium or osmium for the New Zealand and Danish boundary shales, as well as for the Allende meteorite and for crustal material represented by mean values for the Canadian Shield12. The data clearly indicate a non-crustal source for the New Zealand material, and because the values lie well outside the field for mantle material, an extraterrestrial source is indicated.

Our value of 1.12 ± 0.16 (2 σ) for the ¹⁸⁷Os/¹⁸⁶Os isotopic ratio is the same as that reported by Luck and Allègre⁴ for the mean of 10 chondrites (1.11±0.01), suggesting an extraterrestrial source for the osmium. It is true that the ratio is also typical of mantle material but this question has already been dealt with above (see also Fig. 1) and we prefer to propose a probable extraterrestrial origin for the osmium. Certainly the findings clearly negate any arguments that the osmium is of crustal origin. Using our value of 10.4% for the extraterrestrial component of the New Zealand boundary shale3, we can calculate that correction for terrigenous osmium would lower our ratio from 1.12 to 1.10. This is still extremely close to the ratio for chondrites and gives the best evidence so far for the non-crustal origin of the osmium (and by inference also probably the iridium) in the Woodside Creek material.

It is suggested that our combined distillation-extraction-ICPMS procedure will have a continuing use for the determination of osmium isotopic ratios in a wide variety of geological materials. In the application reported here, measurements were made on solutions containing only ~0.15 ng ml⁻¹ of the two osmium isotopes (that is, ~5 ng total osmium), and our combined procedure should prove to be an acceptable alternative to the chemical separation-mass spectrometric ion probe method now in use.

Silicate microspherules intercepted in the plume of Etna volcano

R. Lefèvre*, A. Gaudichet*† & M. A. Billon-Galland†

A possible volcanic origin has been suggested for the micrometresized spherules that have been discovered in polar snows or icecores¹⁻³, and in the stratosphere^{6,7}. However, although such particles, especially when black and magnetic, have been identified among the tephra deposits of some volcanoes^{3,8-12}, their volcanic emission has never been directly observed. Here we describe microspherules intercepted in the plume of Mount Etna, Sicily, during moderate recurring volcanic activity. Their study, using analytical transmission and scanning electron microscopy (ATEM and ASEM) demonstrates the simultaneous presence in the plume of glassy silicate microspherules of various chemical compositions (47-98% SiO₂).

Particles were collected in September 1984 and August 1985 on a Nuclepore membrane (porosity 0.4 µm) by bulk filtration of the aerosol flux emitted by a summit crater of Mount Etna (Bocca Nuova, elevation 3,340 m above sea level). A volume of 2-3 m³ of diluted volcanic plume was filtered at a flow rate of 1 m³ h⁻¹. The sampling head was placed inside the crater at the end of a 6-m-long flexible fishing rod, 2 m beneath and 2 m away from the crater rim. Because the wind blowing onto the crater was weak or moderate during sampling, only rising

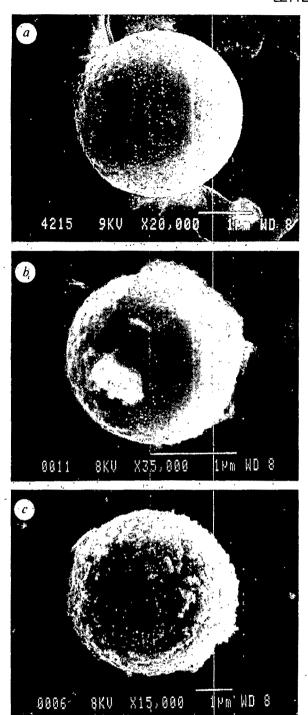

Fig. 1 Scanning electron micrographs of three typical microspherules intercepted in the permanent plume of Mount Etna volcano and washed with filtered distilled water (JEOL JSM 840 electron microscope; accelerating voltage, 8 kV; scale bar, 1 μm). a, Smooth and clean microspherule showing small punctuations; b, Microspherule coated with microparticles, among them a probable feldspar crystal. c, Granular microspherule.

aerosols were collected and these showed no evidence of contamination by wind-blown tephras from the external flanks of the volcano.

The Nucleopore membrane, which has been covered with a carbon layer before sampling, received a second carbon layer after particle collection. The collected particles, trapped between the two carbon layers, were then transferred onto gold grids for analysis by ATEM^{13,14}. This transfer was performed by chloroform dissolution of the membrane under moderate aspir-

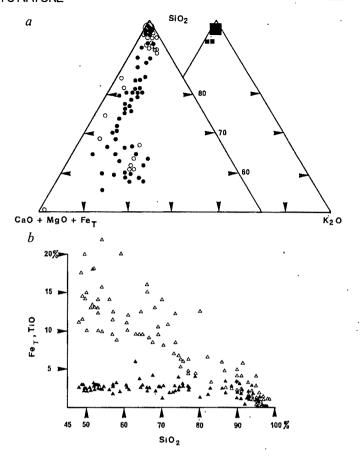

Fig. 2 a, Chemical compositions plotted in an SiO₂ versus K₂O and CaO+MgO+Fe_T diagram of 54 glassy microspherules intercepted in September 1984 (●) and 36 in August 1985 (○), compared with 17 shards of volcanic glass intercepted in September 1984 (■), in the plume of Mount Etna. These diagrams show the variation of the compositions of microspherules and the hypersiliceous composition of shards. b, Relationship between SiO₂ content and Fe_T (△) or TiO₂ (▲) of 90 microspherules. Note the Fe_T decrease linked with the SiO₂ increase. Titanium remains almost constant, except for the most SiO₂-enriched spherules.

ation. For analysis by ASEM the membrane was not dissolved and was placed directly on the specimen holder.

Among the collected particles, non-silicate species (such as sulphates and oxides) are predominant. The silicates consist of crystals (such as feldspars), shards of silicate glass¹⁵ and microspherules. The diameter of the microspherules ranges from 0.1 to 5 μ m and is <2 μ m for 85% of them. The concentration of microspherules was estimated to be $3\times10^6\,\mathrm{m}^{-3}$ in September 1984 and $7\times10^6\,\mathrm{m}^{-3}$ in August 1985. Their external morphology is either smooth and clean (Fig. 1a), coated with fine grains or crystals (Fig. 1b), or granular (Fig. 1c). Electron microdifraction demonstrates the glassy structure for the smallest spherules (0.5 µm in diameter). The individual quantitative chemical composition of the microspherules was obtained by X-ray energydispersive spectrometry using the peak ratio method and taking Si as an internal reference element 16. This is valid if the particles can be considered to be thin layers (<2 µm). The results are highly variable, even within a given sample. In particular, the SiO₂ content ranges from 47 to 98%, that is, from values typical of Etnean lavas (but with a noticeable K-enrichment) to values corresponding to nearly pure silica (Table 1 and Fig. 2). No correlation is observed between morphology, size and composition.

Assuming that each microspherule has a mean diameter of 1.4 µm and a mean density of 2.75 g cm⁻³ (between 2.85 for basalt and 2.26 for tridymite), the 10⁶ microspherules we have

encountered per m³ of filtered air have a total mass $\sim 4 \times 10^{-3}$ mg. The SO₂ discharge from Mount Etna averages $\sim 4 \times 10^3$ tonne day⁻¹, with a mean SO₂ concentration in the plume ^{17,18} of ~ 10 mg m⁻³. The discharge of microspherules can then be roughly estimated at 1.6 tonne day⁻¹.

The genesis of such microspherules and their surprisingly variable chemical composition within the same sample of diluted volcanic plume need to be explained. Some possible hypotheses are discussed below (Fig. 3):

- (1) Contamination of the volcanic plume by industrial fly-ash seems to be excluded: the concentration of fly-ash samples in the same conditions at the periphery of the volcano and the limit of its sedimentary basement (Village of Maletto, elevation 975 m) is a $\sim 10^4$ m³, much lower than the concentration of glassy microspherules in the Mount Etna plume. Moreover, the chemical composition of industrial fly-ash is not commonly hypersiliceous 19,20 , in contrast to a large proportion of our volcanic microspherules. A volcanic origin of these particles is therefore likely.
- (2) The spheroid shape of the particles may be explained by two physical processes of emission: lava fountaining and/or phreato-magnetic eruptions. (a) Spheroidal droplets of glass are produced by highly fluid lava fountaining, as for example in Hawaii^{11,12,21,22}. Intense degassing of fluid lavas allows the dispersal of a spray of liquid magma droplets, which are then rapidly cooled to form simple glass spheres²³. The same mechanism has been proposed for the glass spheres discovered in Apollo 15 and 17 lunar samples²¹. However, the analysis of both terrestrial and lunar spheres has shown that their composition is constant. Therefore, although the mechanism of lava fountaining could be responsible for the presence of microspherules in the Etna plume, it does not explain the chemical variation. (b)Spheroidal-shaped particles have been observed²⁴ by SEM in the debris collected after experimental explosions, simulating phreato-magmatic eruptions produced by the reaction of water with a melted mixture of $Al_2O_3 + Fe$. These particles are very similar to hydrovolcanic ash²⁵. A phreato-magmatic process may thus explain the shape of our microspherules, but cannot account for their variable composition. (c) Whatever the genesis of microspherules (lava fountaining or phreato-magmatic explosions), the stagnation in the air-plume column between magma surface and crater rim of microspherules emitted by magmas of various compositions following one another in the pipe, is not compatible with the monotonous chemistry of the Etnean basaltic lavas produced by lateral eruptions^{26,27} (Table 1). However, note that siliceous xenoliths derived from the sedimentary substratum of Mount Etna have been described in the pyroclastic

products of Mount Rossi and Mount Silvestri eruptions (1669 and 1892), on the southern flank of the volcano²⁸. The mechanism of generation and extraction of this material, in microspherical form, from such partially assimilated xenoliths is difficult to imagine.

- (3) Incipient liquid immiscibility has also been suggested²⁹ to explain the presence of SiO₂-rich spherules (in the micrometre size range) found in the products of the experimental alteration of Etnean basaltic glass by hot water in a Soxhlet apparatus. If such microspherical domains were present in the magma, they would be emitted in the plume directly after solidification at the surface. Such an explanation seems implausible in the present circumstances.
- (4) Pre-existent microspherules could be extracted from weathered tephra deposits falling onto the magma surface before explosive or phreato-magmatic eruptions. The same microspherules found in the weathered tephra deposits on the inner flanks of the crater could be mobilized by the ascending gaseous flux which forms the permanent plume of the Mount Etna volcano. This hypothesis appears to be unlikely, as such structures have not been described in weathered volcanic tephra.
- (5) Volcanic water emission by the Mount Etna plume has been evaluated 18 at $\sim 1.4-2\times 10^5$ tonne day $^{-1}$. This water is mostly meteoric in origin. During its circulation through the volcanic edifice, it would become heated and enriched in silica and ionic salts. At the magma/atmospheric interface, the water is released as vapour, and we may consider that dissolved silica-rich products could then be condensed as microspherules with varying chemical composition.
- (6) Some experiments³⁰ emphasize the role of sulphur reacting with many of the common rock-forming silicates over wide temperature and pressure ranges to produce sulphides, oxides and pure silica. Depending on the amount of SO₂ discharge from Mount Etna^{17,18}, the sulphurization may be an important and suitable process for the generation of SiO₂-enriched microspherules and, depending on the speed of transport, may explain the observed compositional spectrum.
- (7) Combustion of volcanic gases at the magma/atmosphere interface may be responsible for an increase in temperature, causing differential fusion of the solid silicates present in the magma, followed by a quenching of microspherules of various compositions. This mechanism is invoked to explain the fly-ash formation in coal-burning power-station furnaces: their morphology is acquired during cooling of the non-combustible mineral content of the coal, melted at temperatures >1,500 °C, while being carried along with the gaseous combustion products 31,32

Table 1 Typical chemical compositions (oxide weight) of small volcanic glass shards (A to C) and microspherules intercepted in September 1984 (D to H) and August 1985 (I to M) in the permanent plume of Mount Etna, compared with the mean bulk composition of recent lavas and tephras (N)^{26,27}

The volcanic glass shards are always hypersiliceous; the microspherules vary from a typical Etna composition (with K-enrichment) to hypersiliceous composition (the Na-depletion is probably an artefact). Analyses were performed by ATEM (JEOL 100C fitted with an energy-dispersive x-ray spectrometer EDAX 711).

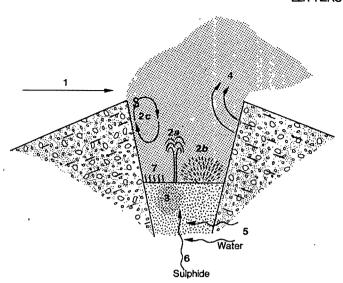

Fig. 3 Illustration of the hypotheses proposed in the text to explain the genesis and variable chemical composition of microspherules intercepted in the permanent plume of Mount Etna. (1), Contamination by industrial fly-ash; (2a) lava fountains; (2b) phreato-magmatic explosions; (2c) stagnation in the crater of different generations of microspherules emitted by successive magmas; (3) extraction of microspherules from SiO2-enriched domains in the magma (incipient liquid immiscibility). (4) extraction of pre-existent microspherules from weathered tephras; (5) dissolution by meteoric water, followed by water-emission and condensation of silica-rich products; (6) interaction between sulphur and silicates and/or magma to produce sulphides, oxides and silica; (7) combustion of volcanic gases and quenching of magmatic silicates; S, sampling location.

In the present state of our study, the more plausible hypotheses seem to be (2a), (5), (6) and (7) or a combination of these: the dissolving properties of water for silica at high temperatures and sulphurization of silicates are probably involved to produce SiO₂-enriched microspherules; the lava fountains^{33,34} and similar phenomena involving gas emissions occur at Etna and, finally, the surprising morphological analogies between Etnean glassy microspherules and industrial fly-ash generated in power plant furnaces suggest similar thermal conditions.

Sewage sludge as an acidity filter for groundwater-fed lakes

W. Davison

Freshwater Biological Association, The Ferry House, Ambleside LA22 OLP, UK

The acidification of lakes by acid rain has increased awareness of the problems associated with acid waters¹, and has stimulated work on self-neutralization mechanisms² and liming strategies³. However, some very acid lakes, particularly those which have been newly formed by the widespread extraction of coal, mineral ores and sand and gravel, owe their acidity to another source. If pyrite is present, as it often is, its exposure to air induces microbially mediated oxidation, resulting in the production of sulphuric acid4. The waters of the lakes then resemble dilute acid, typically with pH < 3, with an impoverished flora and fauna. Neutralizing such waters with lime ameliorates the situation, but only temporarily because further supply of acidic groundwater inexorably lowers the pH. Here I report the use of a combined treatment of lime and sewage sludge, which has produced a self-regulating system, capable of maintaining a stable pH. The organic material which is spread over the bottom of the lake acts as a chemical filter, removing acidic sulphate as it enters, and converting it to neutral sulphide.

The use of sewage sludge for lake reclamation was tested in a pilot scheme. British Industrial Sand Ltd provided a small $(3.6 \times 10^4 \text{ m}^2)$ lake, Blue Lagoon, which had been formed by excavating sand below the water table at their Leziate site, near King's Lynn, Norfolk, England. It had no inflows, negligible catchment, a maximum depth of 4.5 m and a mean depth of 1.5 m. Over the past 10 years, during which time it had remained undisturbed, its waters had been consistently acid $(pH \sim 3)$. Analysis showed that the major acid components were H₂SO₄, 0.35 mM, Al₂(SO₄)₃, 0.11 mM and Fe(OH)SO₄, 0.05 mM.

On 3 April 1984, 477 m³ of activated sewage sludge containing 4.2% solids was pumped into the lake through a pipeline which was moved in an arc to cover approximately one quarter of the lake area. On 30 April 1984, 16.98 tonnes of calcium hydrated lime, equivalent to 15.3 tonnes of calcium hydroxide, were added through a submerged pipe to the deepest point.

Within days the sewage sludge settled out to leave clear water. The pH quickly rose to ~ 10 on adding the lime, after which, as carbon dioxide was supplied from the atmosphere, the solubility of calcium carbonate became the controlling factor and the pH stabilized between 7 and 8. To assess the pH without the effects of supply and removal of carbon dioxide by respiration and photosynthesis, it was also recorded after bubbling the sample with air for ≥30 min (Fig. 1). After two years the lake was still neutral.

Many factors may affect the pH, including the residence time of the water and further dissolution of precipitated calcium carbonate. The real test of the scheme is whether, first, sulphate is reduced and removed as sulphide, and, second, the rate of removal of sulphate is sufficient to cope with the further supply of acid from groundwater.

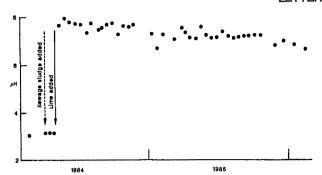

Fig. 1 Air-equilibrated pH of the surface waters of Blue Lagoon, plotted against time. The neutralization reactions involved are: $H_2SO_4 + Ca(OH)_2 = CaSO_4 + 2H_2O$; $AI_2(SO_4)_3 + 3Ca(OH)_2 = 2AI(OH)_3 + 3CaSO_4$; $Fe(OH)SO_4 + Ca(OH)_2 = Fe(OH)_3 + CaSO_4$.

On 27 August 1985, four cores of sediment and overlying water were collected from the deepest site using a Jenkin corer⁵. Analysis of two of the sediment cores revealed contents of organic carbon (11-20%) and acid volatile sulphide (1.2-18 mg per g dry weight) which were higher than would be normally expected for a very productive lake⁶. Evidently, appreciable quantities of sulphate had been reduced.

To quantify the rate and extent of sulphate reduction, two sealed sediment-water cores were incubated in the dark, initially at 17 °C, and then, after replenishing the sulphate-depleted water, at lower temperatures. Analysis of sulphate in the overlying water showed that sulphate was being removed at a rapid rate (Fig. 2), 835 mg m⁻² day⁻¹ at 17 °C and 278 mg m⁻² day⁻¹ at 10 and 4 °C. Knowing the original sulphate concentration of the lake water (\sim 125 mg l⁻¹), and assuming it is the same in the groundwater, one can calculate the minimum water residence time required for the reduction of sulphate to sulphide in the sediment to be able to cope with additional supply of acid from the groundwater. At the rate of consumption for 17 °C the minimum residence time is 6 months; at the lower temperatures it is 1.5 yr. As the mean annual temperature will be within this range, the residence time must exceed 1 yr if the chemical filter is to keep pace with the input of acid. There is evidence to show that at the outset of our study the residence time of Blue Lagoon was ~1 yr, but that it has since progressively increased to several years, presumably due to organic matter clogging the pores of the sand. If reduction of sulphate occurs as efficiently in the lake as in the laboratory experiment, this mechanism alone will prevent re-acidification. When these incubation results are applied to the whole lake, they are equivalent to an annual base production of 0.7-2.1 mequiv. 1⁻¹, which agrees with the figure of 1 mequiv. 1⁻¹ for hypolimnetic water².

So far only the consumption of freshly entering sulphate has been considered, but there is also sulphate already present within the water. Its associated acid was neutralized by the initial lime, so there is no requirement for this sulphate to be consumed to maintain neutrality. The concentration of sulphate, normalized with respect to sodium to compensate for evaporation and dilution effects, is highly variable, but did undoubtedly decline over a 2-yr period (Fig. 3). This indicates that removal of sulphate from the sediment was more than balancing further supply.

If the only supply of organic matter were from sewage sludge, the sediment's capacity for sulphate reduction would soon be exhausted. However, liming and the nutrients associated with the sludge stimulated high biological productivity, so that within a few months of treatment, algal populations were typical of a eutrophic pond. Thus, additional carbon, originating as atmospheric CO₂, is continually supplied to the lake and eventually accumulates as organic-rich sediment. Photosynthesis is effectively used, through artificially induced eutrophication, to combat acidification.

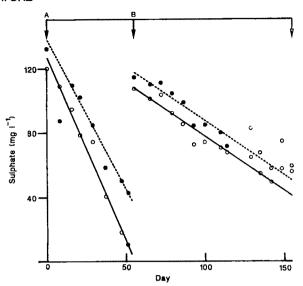

Fig. 2 Sulphate concentrations in the waters overlying the sediment of two sealed cores incubated in the dark. Initially (A-B) they were maintained at 17 °C, after which (at point B) the overlying waters were exchanged, under anoxic conditions, with water from the lake that had been deoxygenated using an Ar-CO₂ gas mixture to leave the pH unaltered. One core (O) was then incubated at 10 °C and the other (●) at 4 °C.

This scheme of permanent neutralization will be most effective when applied to large lakes with flat bottoms and deep water. Deep water (>5 m) prevents disturbance of the organic-rich sediment by wind-induced water movements, and flat bottoms help to ensure that the covering is uniform. Reduction of sulphate occurs readily in a sediment overlain by oxygenated water, but it proceeds with greater efficiency if the overlying waters become anoxic, a situation encouraged by depths >5 m. Covering the sediment with reducing organic material cuts off an important supply of oxygen to the groundwater. This limitation of oxygen, which will decrease the rate of production of acid from pyrite, will be more effective, the greater the area of the lake.

Unfortunately, the only experimental site available, Blue Lagoon, is smaller and shallower than ideally required, according to the above criteria. It is not surprising, then, that the pH appears to be slowly declining (Fig. 1), indicating that the lake may return to an acidic state. However, sulphate has been consumed by the sewage sludge and photosynthesis will continue the process, so the new equilibrium pH which will event-

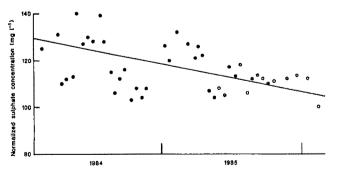

Fig. 3 Concentration of sulphate in Blue Lagoon, normalized with respect to the concentration of sodium. Normalized SO_4^{2-} concentration = $[SO_4^{2-}]_t \times [Na^+]_{in}/[Na^+]_t$, where the subscripts 'in' indicates initial concentration, and t the concentration at time t. Acidity removal is accomplished by the reduction of sulphate and ferric iron by organic material, and their precipitation as ferrous sulphide: $SO_4^{2-} + 2H^+ + Fe(OH)_3(s) + 9/4$ $CH_2O = FeS(s) + 9/4$ $CO_2 + 19/4$ H_2O .

ually be established will be higher than the original value. Thus, the feasibility of using organic material as a chemical filter for acidity has been established. The effectiveness of the scheme will vary from lake to lake, depending on the relative fluxes of acid and base. For lakes of appropriate morphology this scheme offers the possibility of permanent neutralization from one initial treatment.

One of the main features of this scheme is the use of organic matter to provide a chemical filter to neutralize the supply of acid from groundwater. Lakes affected by atmospheric acidification are not usually supplied with acid groundwater, except perhaps those in a peat terrain. However, introducing organic carbon, by adding sewage sludge or by adding nutrients to stimulate primary productivity, may still effectively combat acidification. Even in acidic conditions⁸, the decomposition of organic material will introduce base². The level of base production measured in this and other studies², ~ 1 mequiv. 1^{-1} yr⁻¹. is large compared with the acidity of rainwater, which at pH 4 is 0.1 mequiv. 1⁻¹. Evidently, by artificially inducing eutrophication, sufficient base can be produced to neutralize acidification from atmospheric sources. Further work is urgently needed to test such schemes and to compare them with liming strategies.

I thank BIS Ltd for sponsoring this work and many BIS and FBA staff for their enthusiastic involvement.

Climatic influence on the isotopic composition of bone nitrogen

Tim H. E. Heaton, John C. Vogel, Gertrud von la Chevallerie & Gill Collett

Natural Isotopes Division, National Physical Research Laboratory, CSIR, Pretoria, South Africa

The 13C/12C isotope ratios in animal and human bone can be used as indicators of diet, more recently it was shown that the ¹⁵N/¹⁴N ratios of animals and humans are similarly determined by the food they eat³⁻⁵. Specifically, the stable carbon isotope composition reflects the proportion of C₃ and C₄ plants at the base of the food chain^{1,2}, while both ¹⁵N and ¹³C reveal the difference between a marine and terrestrial diet in modern as well as archaeological contexts⁵⁻⁷. Here we present data for human and animal bones from southern Africa which only partly conform to previously recognized patterns for 15N/14N ratios. Prehistoric human bones from a particular coastal region of South Africa show 15N/14N ratios consistent with the marine and terrestrial diets indicated by the 13C/12C ratios, but bones of both prehistoric humans and modern wild animals from a larger part of the subcontinent show variations in 15N/14N ratios which cannot be ascribed to known variations in diet. It appears that, in some environments, nitrogen isotope studies must also take into account the possible influence of the climate.

Collagen or gelatine was isolated from the bones of protohistoric and prehistoric human skeletons and modern wild herbivorous animals from a variety of climatic/vegetational habitats in South Africa and Namibia (Fig. 1). Isotopic ratios were determined on N2 and CO2 produced by combustion of the

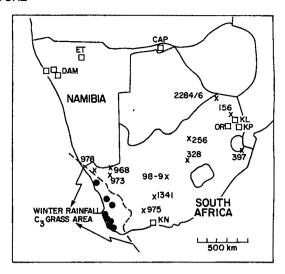

Fig. 1 Locations from which bone samples were obtained. •. Human skeletons from sites 0-60 km from the south-west coast. x, Human skeletons from sites 60-500 km from the coast, laboratory sample numbers are shown.

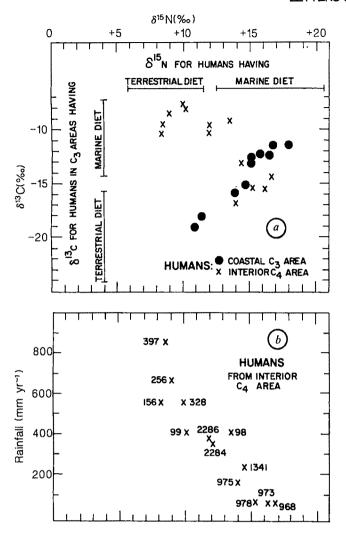

, Herbivorous terrestrial animals from game reserves as indicated (CAP=Caprivi; DAM= Damaraland; ET = Etosha; KL = Klaserie; KN = Knysna; KP = Kruger Park; OR = Origstad dam).

isolates⁸, and on N₂ produced by the Kjeldahl digestion-lithium hypobromite method⁹. The ratios are reported in the usual δ^{15} N and δ¹³C notation versus atmospheric N₂ and PDB carbonate standards, respectively. In all cases the N content of the samples ranged between 14% and 17%, within 10% of the expected value for protein. We therefore do not expect a noticeable postmortem shift in the isotopic values10

The isotopic data indicated by the solid circles in Fig. 2a are for human bones from sites in the southwestern part of South Africa, an area with winter rainfall in which C₃ grasses (and other C₃ plants) predominate¹¹. Sealy and van der Merwe¹². presenting carbon isotope data for a set of samples from the same region, suggest that in this C_3 area a higher $\delta^{13}C$ value in the skeletons reflects a higher marine/terrestrial food ratio in the prehistoric human diet. Data for human bones from other parts of the world indicate that a larger proportion of marine food in the diet should also be reflected by higher δ^{15} N values⁶. The solid circles in Fig. 2a in fact show a close correlation of increasing $\delta^{15}N$ with increasing $\delta^{13}C$, and it appears that in this region the nitrogen isotope data for human skeletons independently confirm the marine/terrestrial dietary interpretation of the carbon isotopes.

Human skeletons from a large area in the interior of South Africa (crosses in Fig. 2a) have $\delta^{15}N$ values similar to those of skeletons from the south-west coast, extending into the range of $\delta^{15}N$ for a marine diet. The samples from the interior, however, were from sites 60 to 500 km from the nearest coast and, whilst some of the nomadic people may have spent part of their life at the coast, these distances imply that terrestrial rather than marine food would have formed the major component of their diet. The unexpected range of $\delta^{15}N$ values for bones of humans from the interior is moreover also displayed by bones of herbivores feeding exclusively on terrestrial plants. Thus bones of a single herbivorous species, the African Elephant, have $\delta^{15}N$ values from +2.6 to +14.6%—a range which is wider than that previously reported for terrestrial herbivores, and which extends into the range of marine 'herbivores' (Fig. 2c).

Human bones from the interior and all the animal bones were from areas in which C₄ grasses grow among C₃ shrubs and trees. The range in δ^{13} C for the human (Fig. 2a) and animal bones¹

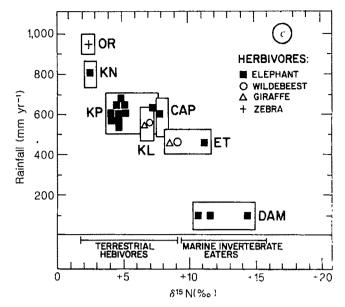

Fig. 2 Nitrogen isotope ratios of human and animal bones, $\delta^{1^4}N$ (in per mil) = {[($^{15}N/^{14}N$)_{sample}/($^{15}N/^{14}N$)_{standard}] - 1) × 10³; the standard is atmospheric N_2 . a, Nitrogen and carbon isotope ratios of humans (symbols as in Fig. 1) compared with the suggested range of isotopic compositions for humans having terrestrial and marine diets⁶. b, Nitrogen isotope ratios of humans from the interior vs. the mean annual rainfall of the collection site (numbers as in Fig. 1). c, Nitrogen isotope ratios of terrestrial herbivores versus the general range of mean annual rainfall for the collection area (letters refer to game reserves listed in Fig. 1). The horizontal bars show the published range of isotopic compositions for bones of terrestrial herbivores and marine invertebrate eaters for comparison5.

in these areas reflects the different 13C/12C ratios for C4 and C3 plants and the variation in grazing versus browsing in the diet. There is no evidence, however, for a related effect on the nitrogen isotopes: C_4 and C_3 plants have similar $\delta^{15}N$ values¹³, and grazers (wildebeest) and browsers (giraffe) from the same area, whilst having very different δ^{13} C values¹, have very similar δ^{15} N values (Fig. 2c). Published analyses for the δ^{15} N values of modern nitrogen-fixing and non-fixing plants differ, on average, by only 2 to 3%13; it therefore appears that the range in bone $\delta^{15}N$ values also cannot be explained in terms of different proportions of leguminous and non-leguminous plants in the diet.

We suggest that the wide range in $\delta^{15}N$ for human and animal bones in southern Africa reflects the very wide range of climatic habitats. In Fig. 2b and 2c the δ^{15} N values of the humans from the interior and of the herbivores are plotted against the mean annual rainfall for the sites from which the bones were collected. Bearing in mind the fact that some of the humans and animals are migratory (elephants moving between Etosha and Damaraland, for example), it nevertheless appears that there is a definite tendency for increasing 15N with increasing aridity. Thus the animal or human bones with $\delta^{15}N$ values higher than +10% or +13% respectively, falling into the range of a 'marine diet' isotopic signature, are from areas receiving less than about 400 mm of rain per year (Fig. 2b, c).

The increase in nitrogen isotope fractionation that is observed in the bones of humans and particular species of ungulates living in arid environments must take place somewhere along the food chain. It occurs either in the plants growing under hot xeric

conditions or in the animals themselves. Measurements on C₃ and C₄ plants from a variety of habitats in southern Africa thus far show no obvious relationship of $\delta^{15}N$ with rainfall or photosynthetic pathway. The higher $\delta^{15}N$ values of animals in arid areas are therefore more likely to be linked with the nitrogen metabolism in the body of the animal itself.

The data presented here indicate that the interpretation of the nitrogen isotope ratios of bones in terms of diet may be more complicated than previous studies suggest, and that the influence of climate also needs to be taken into account. 15N/14N ratios may in fact prove to be a useful tool for studying past climatic variations, especially in areas where large changes in precipitation have occurred.

We thank S. Braine, Möwe Bay, R. Thwaites, Saasveld and A. Hall-Martin, Skukuza, for supplying some of the elephant bone samples, and Siep Talma for supervising mass spectrometric analyses in the laboratory.

Functions of the ON and OFF channels of the visual system

Peter H. Schiller, Julie H. Sandell & John H. R. Maunsell

Whitaker College, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

In the mammalian eye, the ON-centre and OFF-centre retinal ganglion cells form two major pathways projecting to central visual structures from the retina. These two pathways originate at the bipolar cell level: one class of bipolar cells becomes hyperpolarized in response to light, as do all photoreceptor cells, and the other class becomes depolarized on exposure to light, thereby inverting the receptor signal. It has recently become possible to examine the functional role of the ON-pathway in vision by selectively blocking it at the bipolar cell level using the glutamate neurotransmitter analogue 2-amino-4-phosphonobutyrate (APB)1. APB application to monkey, cat and rabbit retinas abolishes ON responses in retinal ganglion cells, the lateral geniculate nucleus and the visual cortex but has no effect on the centre-surround antagonism of OFF cells or the orientation and direction selectivities in the cortex²⁻⁵. These and related findings⁶⁻¹¹ suggest that the ON and OFF pathways remain largely separate through the lateral geniculate nucleus and that in the cortex, contrary to some hypotheses, they are not directly involved in mechanisms giving rise to orientation and direction selectivities. We have examined the roles of the ON and OFF channels in vision in rhesus monkeys trained to do visual detection and discrimination tasks. We report here that the ON channel is reversibly blocked by injection of APB into the vitreous. Detection of light increment but not of light decrement is severely impaired, and there is a pronounced loss in contrast sensitivity. The perception of shape, colour, flicker, movement and stereo images is only mildly impaired, but longer times are required for their discrimination. Our results suggest that two reasons that the mammalian visual system has both ON and OFF channels is to yield equal sensitivity and rapid information transfer for both incremental and decremental light stimuli and to facilitate high contrast sensitivity.

Six monkeys were anaesthetized with halothane and given more than 50 vitreal injections by sterile procedures. The volume of APB used was 75 µl (4-20 mM APB in sterile saline) to yield estimated concentrations of 100-500 µM in the eye. The effects of such injections were assessed in separate experiments with the electroretinogram, since our previous studies had shown that when the ON channel is blocked as determined by single-cell recordings in the lateral geniculate nucleus, the b-wave of the electroretinogram is eliminated 12. Although there is some variability in the exact time-course of APB action with the intravitreal injection method, we found that a single injection was usually effective within 1 h and lasted 3-8 h. With the concentrations used in this study, recovery was complete by the following day. In all cases only one eye was injected and the other was patched.

Monkeys were deprived of water and rewarded with apple juice. Their eye movements were monitored with the scleral search coil technique, and they were rewarded for correctly making saccades to visual stimuli presented on a colour monitor. A PDP 11/73 computer was used to drive the monitor, control the experiment and record and store the eye movement and performance data. All trials began with the appearance of a small central spot. In the detection paradigm, after the animal had made saccades to this spot and maintained fixation on it for 400-800 ms, a target stimulus appeared at one of several randomly chosen locations, and the animal's task was to make saccades to it; the stimulus remained on until it was foveated.

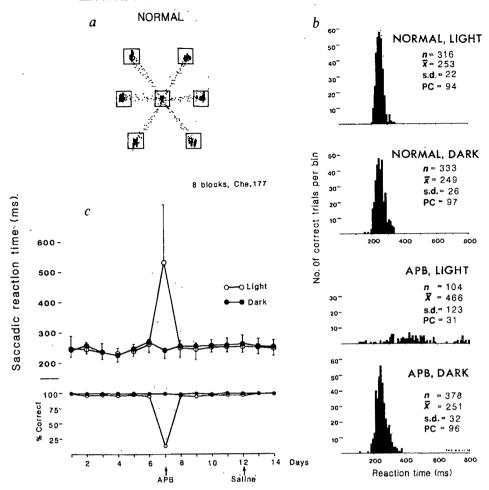

Trials on which saccades were made to locations other than the target were aborted. When the saccade brought the fovea to within 2° of the target centre, it was judged by the programme to be successful and the animal was rewarded with a drop of apple juice. This paradigm, which permits accurate placement of stimuli on selected portions of the retina, is learned rapidly and performed accurately. Trials can be run in close succession without fatigue (with inter-trial intervals of 2–3 s), and monkeys regularly perform 1,500–2,000 trials per day. This permits relatively speedy generation of psychophysical functions. Figure 1a shows eye movement data collected for 48 successive errorless trials in which a target appeared 8 times at each of 6 target locations, showing the normal animal's characteristic, disciplined performance.

To test the hypothesis that the ON channel contributes predominantly to the detection of stimuli seen by virtue of light increment while the OFF channel contributes to the detection of light decrement, we trained monkeys to make saccades to targets which were either lighter than or darker than the background. Figure 1b shows the distribution of saccadic latencies on a set of light and dark stimuli in the normal and APB-injected monkey. One to six hours after APB administration (75 µl of 8 mM APB), there was a pronounced deficit in the detection of light incremental stimuli, accompanied by a large increase and spread in saccadic latencies. Performance on light decremental stimuli was unaffected. Figure 1c shows the monkey's performance over 14 successive days on this task, plotting the saccadic reaction times and the per cent correct performance on one set of light and dark stimuli. The APB was injected on day 7 during this sequence, showing the selective impairment for stimuli brighter than background, and also showing that saline injection of the same volume on day 12 did not affect the animal's performance. Similar effects were obtained using a range of target stimuli measuring 17-220 cd m⁻². We also obtained thresholds for the detection of light stimuli in dark-adapted animals: when the ON channel was blocked, detection thresholds were raised by 1.5-2.0 log units, suggesting that APB has a dramatic effect on the eye's rod system.

We examined several other perceptual functions for which we used discrimination rather than detection tasks. The paradigm was quite similar to that used for the detection of light increment and decrement, but instead of one target, several stimuli appeared after the central spot was fixated. One of these stimuli was different from the rest and the animal's task was to make saccades to this target. The physical characteristics of the stimuli could be varied systematically and were presented in randomized sequences. These tests assessed thresholds for the detection of colour stimuli of different degrees of saturation, the maximal temporal rate of flicker discrimination, minimal stereoscopic depth perception using random-dot stereograms, grating acuity, movement perception using random dot displays and the discrimination of gratings having different orientations. Only mild deficits were found on these tasks when the ON channel was blocked with APB. On all of the tasks, however, there was a consistent increase in the latency to performance, averaging 50 ms.

We also examined the contrast sensitivity of animals following APB administration and found considerable impairment using a variety of contrast sensitivity tests. Figure 2 shows the results from one of these. Monkeys were shown six stimuli, five of which were checkerboards while one was a homogeneous stimulus of the same flux. The animal was trained to make saccades to this homogeneous stimulus. Checkerboards of six different spatial frequencies were used, all at the same contrast, randomized over successive trials within a single block. Different contrasts were used in successive blocks. The stimuli appeared at equally spaced locations around the fixation spot at a distance of 8°. The results show a significant loss in contrast sensitivity, particularly at optimal spatial frequencies, as seen in both the per cent correct and the reaction time data. In other tests a

Fig. 1 a, An x-y frame showing traces of saccades made from a central fixation point to a target presented randomly at one of six positions. Targets are 8° eccentric and are squares subtending 1° of visual angle; data from 48 successive trials are shown. Boxes represent spatial limits set for correct acquisition. b, Distribution of saccadic latencies and per cent correct performance before and after APB injection (75 µl of 8 mM) to light incremental and light decremental stimuli. Base illumination set at 121 cd m⁻². The light stimuli measured 186 and the dark 59 cd m⁻². n, Number of trials per histogram; x, mean; s.d., standard deviation. PC, per cent correct. c, Saccadic reaction times and per cent correct performance on 14 successive days for incremental (circles) and decremental (disks) stimuli. APB (75 µl of 8 mM) was injected on day 7 and saline (75 µl) on day 12. Vertical bars show standard deviations, upward for incremental and downward for decremental stimuli.

two-alternative forced-choice staircase procedure was used in which sinusoidal gratings had to be discriminated from homogeneous stimuli; injections of 450 µM APB resulted in a loss of foveal contrast sensitivity of up to 25%.

These results suggest two possible reasons for the existence of both an ON and an OFF channel in the mammalian visual system. One is to provide a means for transmitting information about both light increment and light decrement with an excitatory process to the central nervous system. Since the maintained activity of retinal ganglion cells is relatively low, the information conveyed by a decrease in activity (for example, the effect of

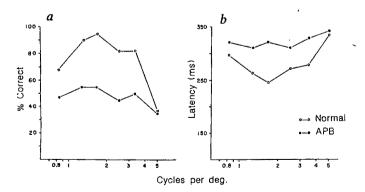

Fig. 2 Per cent correct (a) and mean saccadic latencies (b) on a discrimination task requiring an animal to make saccades to a homogeneous stimulus paired with a set of five checkerboard stimuli; sets were of different spatial frequencies but of the same contrast. Background illumination was 25 cd m⁻², the homogeneous stimulus was 68 cd m⁻² and the high- and lowcontrast checkerboards were 88 and 48 cd m⁻², respectively. Each point is based on 60 trials.

light increment on OFF cells) is difficult to utilize effectively by central visual system neurones, particularly since their maintained activity is even lower than that of retinal ganglion cells. Having both an ON and an OFF channel therefore makes possible efficient information transfer for either sign of contrast change. This is necessary because of the high premium that exists on the speed of information processing in the animal kingdom, both for appetitive and for avoidance behaviours. The second reason for the existence of the ON and OFF channels is to provide increased contrast sensitivity, probably as a result of some form of push-pull interaction between the ON and OFF channels at higher levels in the visual system. High contrast sensitivity is undoubtedly a most desirable attribute for optimal visual function. Neither of these considerations identifies a unique solution to a biological problem. Rapid information transfer and high contrast sensitivity could probably also be accomplished by having a single channel with a rather high maintained discharge throughout the visual system. Such a solution, however, would probably require an unacceptably high rate of metabolic activity.

Expression of functional sodium channels from cloned cDNA

Masaharu Noda, Takayuki Ikeda, Harukazu Suzuki, Hiroshi Takeshima, Tomoyuki Takahashi*, Motoy Kuno* & Shosaku Numa

Departments of Medical Chemistry and Molecular Genetics and * Physiology, Kyoto University Faculty of Medicine, Kyoto 606, Japan

The voltage-gated sodium channel is a transmembrane protein essential for the generation of action potentials in excitable cells1. It has been reported that sodium channels purified from the electric organ of the electric eel, Electrophorus electricus^{2,3}, and from chick cardiac muscle⁴ consist of a single polypeptide of relative molecular mass $(M_r) \sim 260,000$, whereas those purified from rat brain⁵ and from rat^{6,7} and rabbit skeletal muscle⁷ contain, in addition to the large polypeptide, one or two smaller polypeptides of M, 33,000-43,000. The primary structures of the Electrophorus sodium channel⁸ and two distinct sodium channel large polypeptides⁹ (designated as sodium channels I and II) from rat brain have been elucidated by cloning and sequencing the complementary DNAs. The purified sodium channel preparations from *Electrophorus* electroplax¹⁰ and from mammalian muscle^{11,12} and brain¹³⁻¹⁵, when reconstituted into lipid vesicles or planar lipid bilayers, exhibit some functional activities. The successful reconstitution with the Electrophorus preparation would imply that the large polypeptide alone is sufficient to form functional sodium channels. However, studies with the rat brain preparation suggest that the smaller polypeptide of M_r 36,000 is also required for the integrity of the saxitoxin (STX) or tetrodotoxin (TTX) binding site of the sodium channel¹⁶. Here we report that the messenger RNAs generated by transcription of the cloned cDNAs encoding the rat brain sodium channel large polypeptides, when injected into Xenopus oocytes, can direct the formation of functional sodium channels.

Recombinant plasmids that carry the bacteriophage SP6 promoter^{17,18}, linked to the entire protein-coding region of the cDNA for rat sodium channel I (pRI-4 with the 33-nucleotide insertion⁹ or pRI-3 without the insertion) or sodium channel II (pRII-2), were constructed (Fig. 2). Plasmid transcription in vitro by SP6 polymerase generated mRNAs specific for the respective sodium channel large polypeptides (Fig. 1). The estimated sizes of the mRNAs agree with those expected from the structure of the plasmids, except that smaller RNA species were contained in the preparations derived from pRI-3 and pRI-4.

Xenopus oocytes that had been injected with the sodium channel II-specific mRNA derived from pRII-2 and then incubated for 3-6 days showed a transient inward current when the holding membrane potential was shifted from -100 mV to -10 mV under voltage clamp. Following application of TTX (0.3 µM), the inward current was progressively diminished and disappeared within a few minutes (Fig. 3a). Similarly, STX (0.3 µM) blocked the inward current completely. The effects of both the toxins were reversible. In Ringer's solution, the maximum inward currents induced by the sodium channel IIspecific mRNA ranged up to 26 µA, being much larger than those observed in oocytes injected with poly(A)+ RNA from rat brain (up to 1.5 µA) (see also refs 19, 20). On the other hand, oocvtes injected with the sodium channel I-specific mRNA showed only a small response; the mRNA derived from pRI-3 evoked maximum inward currents up to ~50 nA, which were TTX-sensitive, whereas the mRNA derived from pRI-4 induced no detectable currents. Because of the low signal-to-noise ratio for the response evoked by the sodium channel I-specific mRNAs, we restricted our further analysis to the current induced

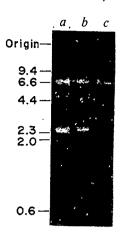

Fig. 1 Electrophoretic analysis of the mRNAs synthesized in vitro using pRI-3 (a), pRI-4 (b) or pRII-2 (c) as template. Samples of the mRNAs (5 μ g in a, b; 1.3 μ g in c) were denatured with 1 M glyoxal and 50% dimethyl sulphoxide³³ and electrophoresed on a 1.5% agarose gel in 10 mM sodium phosphate buffer (pH 7.0). RNA was visualized by staining with ethidium bromide. The size markers used were the HindIII cleavage products of phage λ DNA (sizes in kilobases). The estimated size of the largest mRNA species on each lane agrees with the expected size (~6.7, ~6.7 and ~6.5 kilobases, respectively, in a, b and c).

by the sodium channel II-specific mRNA and compared its properties with those of the current induced by poly(A)⁺ RNA from rat brain.

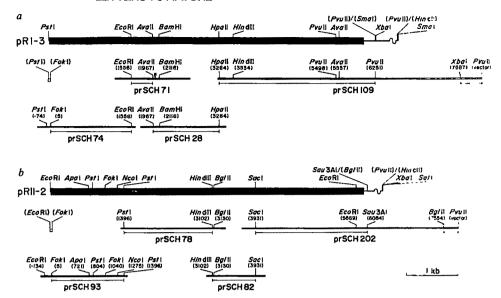

Figure 3b shows an example of the dose-response curves for TTX obtained from oocytes injected with the sodium channel II-specific mRNA. The apparent dissociation constant for TTX (K_{TTX}) ranged from 10 nM to 14 nM. This was comparable to the K_{TTX} value (6-7 nM) obtained for the sodium channels produced in oocytes injected with rat brain poly(A)⁺ RNA; the latter value is similar to that reported previously (9-10 nM)^{19,20}.

When the external Na+ concentration was lowered by replacement with tetraethylammonium, tetramethylammonium or sucrose, the TTX-sensitive inward current was reduced in a dose-dependent manner, being virtually abolished at ~3 mM Na⁺ (Fig. 4a). The fast Na⁺ current observed in the injected oocytes differed clearly from the persistent Na⁺ current which can be induced in native oocytes only by prolonged depolarization and is blocked by TTX only at a dose of ~0.5 mM (refs 21, 22). The fast Na⁺ current was not detected in non-injected oocytes. Figure 4b exemplifies current recordings in Ringer's solution that were made when the oocyte membrane potential was stepped from -100 mV to various levels between -51 mV and +59 mV. In these records, the TTX-insensitive components were subtracted. The peak current-voltage (I-V) relationship obtained by this procedure is shown in Fig. 4c. The maximum current occurred in a range of -12 to +2 mV. This range was similar to that observed for the Na+ current measured in oocytes injected with rat brain poly(A)+ RNA (-8 to 0 mV) (see also refs 19, 20). From the internal Na+ concentration measured in Xenopus oocytes^{23,24}, the reversal potential of the Na⁺ current would be expected to be 40-66 mV. However, the inward current was not reversed at potential levels up to 80 mV. A decrease in the external Na⁺ concentration from 118 mM to 80 mM reduced the inward current, but again failed to reverse the current. A significant permeation of Ca2+ through the TTX-sensitive channel was unlikely because the inward current was not affected by replacement of external Ca²⁺ with equimolar Mn²⁺ or by an increased Ca2+ concentration (20 mM). The TTX-sensitive inward current observed in oocytes injected with rat brain poly(A)+ RNA was also unaffected by Ca2+-free saline, in

Fig. 2 Construction of recombinant plasmids used for expression of rat sodium channel I (pRI-3) (a) and sodium channel II (pRII-2) (b). Only relevant restriction endonuclease sites are shown and identified by numbers indicating the 5'terminal nucleotide generated by cleavage (for nucleotide numbers, see ref. 9); endonuclease sites that no longer exist in pRI-3 or pRII-2 and those corresponding to the ends of the synthetic linkers (indicated by narrow open boxes) are parenthesized. Protein-coding regions are represented by solid boxes, 5'- and 3'-noncoding regions and vector sequences immediately following the poly(dA) · poly(dT) tract by solid lines, and poly(dA) poly(dT) tracts by wavy lines. The cDNA clones used for the construction are indicated by thick lines, and their fragments constituting pRI-3 or pRII-2 by bars underneath. The 33-nucleotide insertion in prSCH71 is shown by an inverted triangle. A scale of 1 kilobase pair (kb) is given.

Methods. The pSP64 (ref. 18) recom-

binants carrying the cDNA for rat brain sodium channel I with (pRI-4) or without

the 33-nucleotide insertion (pRI-3) were constructed as follows. To delete the ATG triplet composed of nucleotides –8 to –6 in the 5'-noncoding region, the synthetic oligonucleotide linker' was prepared using an automatic DNA synthesizer (Applied Biosystems). The ~19-kb FokI(5)/FokI (on vector DNA) fragment from prSCH74 was ligated with the synthetic linker and cleaved with FcoRI. The ~16-kb fragment formed was isolated and cleaved with FxI. The resulting PstI/EcoRI fragment and the ~2.7-kb EcoRI/PstI fragment from pUC18 (ref. 30) were ligated to yield pURI-1. The PstI(~74)/EcoRI(1,556) fragment from prSCH74, the EcoRI(1,556)/AvaII(1,957) fragment from prSCH71, the AvaII(1,967)/BamHI(2,116) and BamHI(2,116)/HpaII(3,264) fragments from prSCH28. The HpaII(3,264)/HindIII(3,534) fragment from prSCH109 and the ~3.0-kb HindIIII/PstI fragment from pSFG5 (ref. 18) were ligated to yield pSRI-A, which was used to construct pRI-3; for the construction of pRI-4, the EcoRI(1,556)/BamHI(2,116) fragment from prSCH71, instead of the EcoRI(1,556)/AvaII(1,967) fragment from prSCH71 and the AvaII(1,967)/BamHI(2,116) fragment from prSCH28, was used to yield pSRI-B. The PvuIII(5,498)/PvuIII(6,251) fragment of 1,945 (or 1,978) base pairs (bp) from pSRI-A (or pSRI-B), the HindIII (3,534)/AvaII(5,557) fragment from prSCH109, the 703-bp AvaIII/XbaI (on vector DNA) fragment from pURI-2 and the ~3.0-kb XbaI/EcoRI fragment from pURI-3 and the ~3.0-kb XbaI/EcoRI fragment from pURI-4 (or pURI-B), the ~0.4-kb XbaI (7,887)/PvuII (on vector DNA) fragment from pURI-1, the 4,671-bp (or 4,704-bp) EcoRI/XbaI fragment from pURI-4 (or pURI-B), the ~0.4-kb XbaI (7,887)/PvuII (on vector DNA) for rat brain sodium channel II (pRII-2) was constructed as follows. The synthetic oligonucleotide linkert was prepared to delete the ATG triplet composed of nucleotides ~8 to ~6 in the 5'-noncoding region. The FokI(5)/FokI(1,040) fragment from prSCH39 was ligated with the synthetic linker and cleaved with PstI. The ~0.8-kb fragment from prSCH39, the HindIII(3,102

Fig. 3 Effect of TTX on depolarization-activated whole-cell inward currents in Xenopus oocytes injected with the sodium channel II-specific mRNA. a, Time course. The inward currents were elicited by a 50-ms pulse stepped from -100 mV to -10 mV. The five records (from bottom to top) were obtained before and 15 s, 20 s, 35 s and 70 s after superfusion with 0.3 µM TTX, respectively. The response obtained 10 min after washing the TTX solution was 88% of that observed before TTX application. Transient capacitative currents were roughly compensated by a network with three adjustable time constants. b, Dose-response curve obtained from another oocyte. The peak inward current evoked by a step from -100 mV to -10 mV, relative to that observed before TTX application, is plotted against the logarithm of TTX concentration. Each point was obtained 3 min after exposure to a new dose of TTX. The measurements were made in the direction of increasing TTX concentration. The record obtained with ~1 µM TTX was subtracted from the control and those obtained with other doses of TTX. The curve represents the dose-response relation expected from a K_{TTX} of 14 nM (indicated by a horizontal bar) according to the equation $y = (1 + T/K_{TTX})^{-1}$, where T is the TTX concentration.

Methods. Total RNA was extracted from the whole brain of male Wistar rats (~200 g body weight) by the phenol method³⁴, and poly(A)⁺ RNA was isolated by oligo(dT)-cellulose chromatography³⁵. Fractionation of poly(A)^{*} RNA by sucrose gradient centrifugation³⁵ was performed as follows. Poly(A)⁺ RNA (100 μg per tube) was centrifuged in linear sucrose gradients (15-30%, w/v) in a Beckman SW-41 rotor at 40,000 r.p.m. for 16h at 4 °C and 25 fractions were collected from each gradient. The fractions sedimenting more slowly than 28S ribosomal RNA and the remaining fractions were each pooled, extracted with phenol/chloroform, precipitated with ethanol and dissolved in water. Xenopus laevus oocytes were injected with the following RNA preparations separately or in combination: sodium channel I-specific mRNA with or without the 33-nucleotuse insertion (1.0 μg μl⁻¹), the sodium channel II-specific mRNA (0.2 μg μl⁻¹), poly(A)⁺ RNA (1.0 μg μl⁻¹), the slow-sedimenting fraction (<28 S) of poly(A)⁺ RNA (1.6 μg μl⁻¹). The average volume injected was ~50 nl per oocyte. The injected oocytes were incubated at 19 °C for 3-6 days in modified Barth's medium³⁷ containing gentamicin (0.1 mg ml⁻¹) and mycostatin (15 μg ml⁻¹). The follicular cell layer was removed^{26,38} from oocytes prior to electrophysiological measurements. Whole-cell currents were recorded with a two-microelectrode voltage clamp et 20+2 °C in Ringer's solution of the following composition (in mM) unless otherwise specified: NaCl, 115; KCl, 2.5; CaCl₂, 1.8; HEPES (pH 7.4), 5 (containing 2 75 mM Na⁺). The voltage recording electrode was filled with 3 M KCl. The current electrode was filled with a solution of (in mM): CsF, 250; CsCl, 250; EGTA, 50; HEPES (pH 7.4), 10.

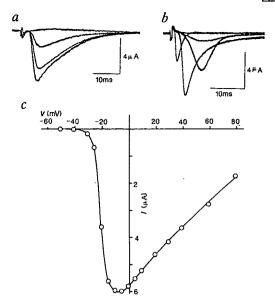

Fig. 4 Properties of depolarization-activated whole-cell inward currents in oocytes injected with the sodium channel II-specific mRNA. a, Effects of changes in external Na⁺ concentration replaced by tetraethylammonium ions. The inward currents were elicited by a 50-ms pulse stepped from -100 mV to -10 mV. The four records (from bottom to top) were obtained at external Na+ concentrations of 118 mM, 80 mM, 41 mM and 2.75 mM, respectively. Each response was recorded 3 min after exposure to a new Na+ level. Transient capacitative currents were roughly compensated by a network with three adjustable time constants. b, Sample records of currents evoked by a voltage step from -100 mV to -51 mV, -25 mV, -21 mV, -6 mV and +59 mV in Ringer's solution. TTX-insensitive currents were subtracted. c, Peak current-voltage relationship by step depolarizations from a holding potential of -100 mV in Ringer's solution. Data from the same oocvte as in b.

agreement with a recent report²⁵. It is possible that, because of the presence of microvilli and indentations on the oocyte surface and the resultant large membrane capacitance²³, the entire plasma membrane is not adequately clamped during the generation of the fast inward current26.

The TTX-sensitive fast current induced by the sodium channel II-specific mRNA showed inactivation following a depolarizing prepulse in a time- and voltage-dependent manner. In view of the large membrane capacitance, the steady-state inactivation was measured with a test pulse to 0 mV following a long (2 s) prepulse stepped from -100 mV to different potential levels (-95 to -10 mV). The potential at which activation of the inward current was 50% (ref. 27) ranged from -61 mV to -57 mV. This range was comparable to that observed for the Na+ current exhibited by oocytes injected with rat brain poly(A)⁺ RNA (-56 to -50 mV) (see also ref. 25).

Our results indicate that the mRNAs derived from the cDNAs encoding the rat brain sodium channel large polypeptides can direct the formation of functional sodium channels in Xenopus oocytes, although the magnitude of the current induced by the sodium channel I-specific mRNA is small. The functional properties of the sodium channels resulting from injection of the sodium channel II-specific mRNA are comparable to those of the sodium channels produced in oocytes injected with poly(A)+ RNA from rat brain. These findings suggest that the sodium channel large polypeptide alone is sufficient to exhibit the function of this channel. The possibility that Xenopus oocytes themselves contain equivalents to the sodium channel small polypeptides, which may associate with the large polypeptide to form functional sodium channels, cannot be excluded. In this context, we observed that a slowly sedimenting fraction (<28S) of rat brain poly(A)⁺ RNA (presumably containing the mRNAs encoding the sodium channel small polypeptides), when injected into oocytes in combination with the sodium channel II-specific mRNA (or the sodium channel I-specific mRNA with or without the 33-nucleotide insertion⁹), did not enhance the TTX-sensitive response. We also observed that a fast-sedimenting fraction (≥28S) of rat brain poly(A)+ RNA alone, in contrast with the slowly sedimenting fraction, induced TTX-sensitive inward currents (up to $1.0~\mu A$) in oocytes, in general agreement with previous reports^{28,29}. The small TTXsensitive response observed in oocytes injected with the sodium channel I-specific mRNA may be due to inefficient synthesis, modification or transport of the channel protein or to the intrinsic properties of this particular sodium channel.

This investigation was supported in part by research grants from the Ministry of Education, Science and Culture and the Science and Technology Agency of Japan, the Mitsubishi Foundation and the Japanese Foundation of Metabolism and Diseases.

Analysis of T-cell subsets in rejection of K^b mutant skin allografts differing at class I MHC

Amy S. Rosenberg, Toshiaki Mizuochi & Alfred Singer

Immunology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20892, USA

The T-cell subpopulations which initiate and mediate tissue allograft rejection remain controversial1-5. In the present study we attempted to identify the phenotype and function of the T-cell subset(s) primarily responsible for the rejection of skin allografts differing at a single class I locus in the major histocompatibility complex (MHC). We found that the rejection rates by B6 mice $(H-2^b)$ of four different class I mutant (K^{bm}) skin allografts form a distinct hierarchy. This hierarchy correlates strikingly and uniquely with the relative precursor frequencies of Lyt2+ interleukin-2-secreting T-helper cells reactive against the various K^{bm} mutants. To investigate the role of Lyt2+ T cells in the rejection of class I-disparate skin allografts directly, H-2b nude mice were engrafted with Kbm skin allografts and then reconstituted with L3T4⁺ or Lyt2⁺ T-cell subpopulations from syngeneic H-2^b mice. Lyt2+ T cells were observed to be both necessary and sufficient for the rejection of class I-disparate K^{bm} skin allografts, whereas L3T4+ T cells were neither necessary nor sufficient. These results identify the Lyt2+ interleukin-2-secreting T-cell subset as the critical cell type determining the rejection rate of class I-disparate K^{bm} skin allografts.

Because the cellular mechanisms involved in allograft rejection are likely to be diverse and dependent upon the antigenic disparity expressed by the graft, we limited our present study to the rejection of skin allografts expressing isolated class I MHC disparities. We chose to investigate the rejection of skin allografts from K^b mutant mice^{6,7} by normal B6 mice because (1) each K^b mutant strain in theory differs from wild-type B6 mice only in the expression of a mutant H-2Kb molecule; (2) each Kbm class I molecule is well characterized biochemically8; (3) the various K^{bm} mutations alter the K^{b} molecule differently so that they are of varying antigenicity9,10. In the first set of experiments, female B6 mice were engrafted with female bm1, bm3, bm6 or bm10 skin allografts. Each graft was scored daily until rejection or day 150. As can be seen in Fig. 1, the rejection rates form a distinct hierarchy, in which bm1 skin allografts are rejected most rapidly, with a median survival time (MST) of 16 days; bm3 and bm10 skin allografts are rejected less rapidly (MST = 22 days) and bm6 skin allografts are rejected least rapidly, the majority of bm6 skin allografts being retained over the 150 days they were followed. A second bm6 skin allograft on mice that failed to reject their initial bm6 graft was also not rejected (data not shown). Nevertheless, the Kbm6 molecule is not itself defective in triggering skin allograft rejection since bm6 skin allografts are rapidly rejected by control bm1 hosts (MST=17 days) which, unlike normal B6 hosts, can react against both mutant and wild-type epitopes on the Kbm6 molecule.

We hoped to identify the function and phenotype of the T-cell subset(s) primarily responsible for the observed hierarchy of B6 anti- K^{bm} rejection rates by assessing *in vitro* the precursor frequencies of the various K^{bm} -reactive T-cell subpopulations present in the spleens of normal B6 host animals. We assessed two distinct T-cell functions: (1) cytolytic activity as assayed by the ability to specifically lyse 51 Cr-labelled target cells following stimulation with spleen cells from each K^{b} mutant strain, and (2) helper activity mediated by interleukin-2 (IL-2) and assayed by the ability to secrete IL-2 in response to stimulation with mutant spleen cells 11 . Fractionated L3T4 $^{+}$ or Lyt2 $^{+}$ T-cell sub-

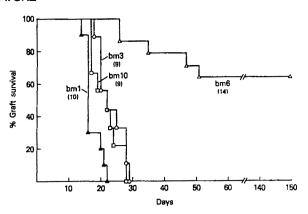

Fig. 1 Rejection of K^{bm} skin allografts by B6 mice. Female B6 mice were engrafted with a tail-skin allograft from female bml (Δ) , bm3 (\bigcirc) , bm6 (\triangle) or bm10 (\square) mice using an adaptation of the method of Billingham and Medawar²⁹. Grafts were scored daily until rejection or day 150. Numbers in parentheses indicate the number of mice in each group. Control B6 grafts were not rejected.

populations were obtained from the spleens of normal B6 mice by pretreatment with either anti-Lyt2.2 or anti-L3T4 monoclonal antibody and complement. The average precursor frequency determinations from several limiting dilution experiments are shown in Table 1, together with the skin graft rejection rates determined from Fig. 1. The precursor frequencies of anti-Kbm L3T4⁺ cytolytic T lymphocytes (T_c) are not given in Table 1 because none were detected¹². In contrast, anti-K^{bm} L3T4⁺ IL-2-secreting helper (T_h) cells were detected, consistent with previous observations that L3T4+ T cells recognize class I alloantigens in the context of self-Ia determinants and function as IL-2-secreting T_h cells but not as T_c effectors in class I allospecific responses ¹³⁻¹⁵. It can be seen in Table 1 that bm1-reactive T cells were the most frequent of any of the anti-K^{bm} specificities examined, regardless of the function or phenotype of the T-cell subset assessed. This result is consistent with the observation that bml skin allografts were the most rapidly rejected, but is unhelpful in identifying the T-cell subset(s) primarily responsible for determining allograft rejection rate. It can also be seen in Table 1 that the precursor frequencies of anti-bm6 cells were approximately equal to the precursor frequencies of anti-bm3 and anti-bm10 cells in both unseparated and L3T4* Th-cell populations, as well as in both unseparated and Lyt2+ T_c populations. These results are markedly discordant with the slow and variable rejection of bm6 versus bm3 or bm10 skin allografts, and suggest that none of these T-cell subsets is the one primarily responsible for determining the rejection rate of class I-disparate K^{bm} skin allografts. However, most interestingly, it can be seen in Table 1 that the relative precursor frequencies of Kbm-reactive T cells in the Lyt2+ IL-2-secreting Th-cell subset correlate perfectly with the rates at which skin allografts from these various mutant strains are rejected. Most B6 mice fail to reject bm6 skin allografts and B6 spleen-cell populations contain few, if any, T cells that secrete IL-2 in response to bm6 stimulator cells. The K^{bm6} molecule effectively triggers Lyt2* T cells from H-2Kk mice to secrete IL-216, so that the failure to detect significant numbers of bm6-reactive Lyt2⁺ IL-2 secreting T cells in B6 mice reflects their low frequency and is not the result of a unique defect in the ability of the K^{bm6} molecule to trigger Lyt2+ T cells to secrete IL-2. These data imply that the number of specifically reactive IL-2-secreting Lyt2+ T cells is the limiting and critical determinant of the rate at which rejection of K^{bm} skin allografts can occur and suggest that Lyt2 T cells in general, and IL-2-secreting Lyt2+ T cells in particular, are required for such allografts to be rejected at all.

To examine the role of Lyt2⁺ T cells in the rejection of class I-disparate K^{bm} skin allografts directly, we made use of an experimental model in which isolated T-cell subpopulations can

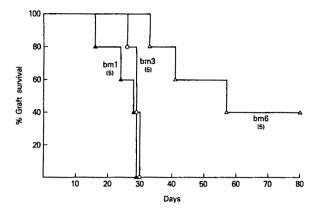

Fig. 2 Rejection of K^{bm} skin allografts by reconstituted B10 nude mice. Female B10 nude mice were engrafted on day 0 with tail-skin allografts from female bml (\triangle), bm3 (O) or bm6 (\triangle) mice. On day 1, each mouse was injected intravenously with 50×10^6 untreated spleen cells from unprimed B6 female mice. Grafts were scored daily until rejection or day 80. Numbers in parentheses indicate the number of mice in each group. MST in days were as follows: bml = 28, bm3 = 29, bm6 = 57. Control B6 grafts were not rejected.

be assessed for their ability to mediate skin allograft rejection after transfer into T-cell-deficient nu/nu mice¹⁷, H-2^b nude mice were engrafted with skin allografts on day 0, reconstituted with 50×10⁶ H-2^b spleen cells or spleen cell subpopulations on day 1, and then examined daily for the status of their skin grafts. To ascertain that skin graft rejection in this experimental model depended upon the adoptive transfer of immunocompetent T cells, we engrafted B10 nude mice with B10.BR (H-2k) skin and reconstituted them with 50×10⁶ spleen cells from either normal or T-cell-deficient, nude B10 mice. The H-2k skin allografts were rapidly and completely rejected by nude mice reconstituted with normal B10 spleen cells (MST=14 days) but were not rejected by any of the nude mice reconstituted with T-celldeficient, nude B10 spleen cells (MST>33 days). To determine if the mechanisms of skin graft rejection in this experimental model reflect those operative in normal mice, we engrafted B10 nude mice with bm1, bm3 or bm6 skin allografts and reconstituted them with normal B6 spleen cells (Fig. 2). Precisely the same hierarchy of rejection rates was observed as had been seen in normal mice, namely bm1>bm3 » bm6, suggesting that similar rejection mechanisms are involved (Fig. 2). Finally, to identify the phenotype of the T cells able to effect the rejection of class I-disparate Kbm allografts, we engrafted B10 nude mice with bml skin allografts and then reconstituted them with 50× 10⁶ untreated normal B6 spleen cells or 50×10⁶ normal B6

spleen cells that had been depleted either of Lyt2+ cells or of L3T4⁺ cells (Fig. 3). The depletion procedures were >99% effective as shown by immunofluorescence and flow microfluorometry (data not shown). The results (Fig. 3) demonstrated that the isolated Lyt2+ T-cell population was both necessary and sufficient to reject bm1 skin allografts. Interestingly, nude mice reconstituted with the isolated Lyt2+ T-cell population rejected bm1 skin allografts more rapidly (MST = 10 days) than did nude mice reconstituted with unfractionated T-cell populations containing both Lyt2⁺ and L3T4⁺ T cells (MST = 22 days), indicating that L3T4⁺ T cells do not synergize with Lyt2⁺ T cells to effect the rejection of bm1 skin allografts and that they might conceivably interfere with the rejection. Finally, nude mice reconstituted with the isolated L3T4⁺ T-cell population were incapable of rejecting bm1 skin allografts (MST >60 days) (Fig. 3), although they were immunocompetent as indicated by their rapid rejection of control class II-disparate skin grafts (data not shown).

The present study provides strong support for the role of Lyt2⁺ T cells in general, and IL-2-secreting Lyt2⁺ T cells in particular, in skin allograft rejection. It significantly extends earlier observations¹⁸⁻²² by demonstrating that Lyt2⁺ T cells are not only able to mediate allograft rejection but are the predominant T cells in the rejection of class I-disparate K^{bm} skin allografts. Interestingly, the presence in B6 mice of both K^{bm}-

[†] Summary of seven experiments. Each limiting-dilution titration consisted of 6-8 experimental points, representing 24-48 replicate cultures. Individual 0.2-ml cultures contained graded numbers of untreated or fractionated responder spleen-cell populations, 5×10^5 2,000R-irradiated stimulator spleen cells and 0.01% (v/v) ascites of 7D4 monoclonal antibody²⁵, specific for the murine IL-2 receptor. The addition of monoclonal anti-IL-2 receptor antibody to the response cultures significantly improves the accuracy of IL-2 production measurements by blocking the consumption of IL-2 during the culture period without interfering with either the production of IL-2 or its subsequent measurement¹¹. After 5 days of culture at 37 °C and 5% CO₂, 0.1 ml of supernatant was collected from each well and assayed for their ability to maintain the proliferation of 4×10^3 indicator HT-2 cells²⁶. Individual cultures were considered positive if the ³H-thymidine incorporation by HT-2 cells in response to their supernatant was more than 3 s.d. above that stimulated by medium alone. Minimal estimates of the frequencies of T_h cells were calculated by analysis of the Poisson distribution relationship between the percentage of negative cultures per group and the number of responding cells²⁷. The T-cell fractionation procedures using monoclonal anti-L3T4 and anti-Lyt2 antibodies are described in Fig. 3 legend.

[‡] Summary of two experiments. Each limiting-dilution titration consisted of 6-8 experimental points, representing 24-48 replicate cultures. Individual 0.2-ml cultures contained graded numbers of untreated or fractionated responder spleen-cell populations, 5×10^5 2,000R-irradiated stimulator spleen cells, and 12.5% supernatant from concanavalin A-induced spleen-cell cultures²⁸, to which α -methyl mannoside had been added. After 7 days of culture at 37 °C and 7.5% CO₂, 4×10^3 51Cr-labelled concanavalin A-induced spleen blast cells were added to each culture as target cells in a 4-h 51Cr-release assay. Cultures were considered positive if their 51Cr release was 3 s.d. above spontaneous release. Minimal estimates of the frequencies of T_c precursors were calculated as previously described²⁷. The T-cell fractionation procedures are described in Fig. 3 legend.

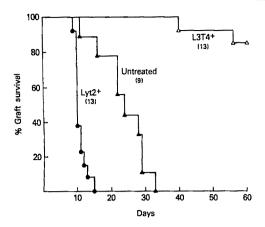

Fig. 3 Ability of isolated T-cell subpopulations to reject bm1 skin allografts. Female B10 nude mice were engrafted on day 0 with tail-skin allografts from female bm1 mice. On day 1, the mice were injected intravenously with 50×10⁶ B6 spleen cells which: were untreated and so contained both L3T4⁺ and Lyt2⁺ T-cell subpopulations (A); had been pretreated with anti-Lyt2.2 monoclonal antibody+complement and so contained only the L3T4+ T-cell subset (Δ); had been pretreated with anti-L3T4 monoclonal antibody+complement and so only contained the Lyt2+ T-cell subset (). Numbers in parentheses indicate the number of mice in each group. Grafts were scored daily until rejection or day 60. MST in days of bm1 skin allografts on B10 nude mice reconstituted with various T-cell populations were as follows: Lyt2+ T cells = 10; unfractionated T cells = 22; L3T4+ T cells > 60.

Methods, Anti-L3T4 monoclonal antibody was a culture supernatant of the hybridoma cell line GK1.5 (ref. 30) provided by Dr Frank Fitch. Anti-Lyt2.2 monoclonal antibody was a culture supernatant of the hybridoma cell line 83-12-5 provided by Dr Jeffrey Bluestone. Depletion of L3T4+ T cells or Lyt2+ cells was accomplished by incubating spleen cells at a density of 107 cells ml-1 with anti-L3T4 (1:2 dilution of culture supernatant) or anti-Lyt2.2 monoclonal antibody (1:5 dilution of culture supernatant) for 30 min on ice. Cells were then pelleted, resuspended and incubated with complement for 40 min at 37 °C. Treated cells were washed three times before injection into experimental animals or before addition to experimental cultures. Efficacy of each treatment (>99%) was confirmed by immunofluorescence and flow microfluorometry. Spleen cells from each group of engrafted and adoptively reconstituted nude mice were assessed 30 days after reconstitution by immunofluorescence and flow microfluometry for numbers of L3T4⁺ and Lyt2⁺ T cells. Spleens from bm1 engrafted nude mice reconstituted 30 days previously with L3T4⁺ T-cell populations contained <1% Lyt2⁺ T cells, whereas spleens from bm1 engrafted nude mice reconstituted 30 days previously with Lyt2+ T-cell populations contained <1% L3T4⁺ cells.

reactive L3T4+ Th and Lyt2+ Tc is not predictive of whether or not Kbm skin is rejected, even though these two T-cell subpopulations collaborate effectively in vitro to generate Kbm-specific Tc responses^{13,15,23}. Since class I-reactive L3T4⁺ T_h cells recognize a composite determinant composed of class I+class II MHC molecules 13-15, the deficient expression of class I MHC on class II-bearing skin epidermal cells²⁴ provides a plausible explanation for the failure of these T_h cells to participate in the rejection of Kbm allografts. Thus, class I-reactive L3T4+ Th cells may never encounter a class (I+II) antigenic complex on individual cells within a skin allograft.

In conclusion, the present study makes three points regarding the rejection of class Î-disparate Kbm skin allografts by wild-type H-2^b mice: first, Lyt2⁺ T cells are the only T cells required to effect the rejection of class I-disparate K^{bm} skin allografts; second, while Lyt2⁺ T_c effectors may contribute importantly to the rejection of K^{bm} skin allografts, it is the number of IL-2secreting, Kbm-reactive T cells within the Lyt2+ T-cell subpopulation that is limiting and that determines the rates at which K^{bm} skin grafts are rejected; and third, potential collaborations

between anti- K^{bm} L3T4⁺ T_h cells and Lyt2⁺ T_c precursors do not have a prominent role in the rejection of K^{bm} skin allografts

We thank Dr Jeffrey Bluestone for helpful discussions and Drs Ronald Gress, Richard Hodes, Susan McCarthy, David Sachs and Dinah Singer for critical readings of the manuscript

Structural/functional similarity between proteins involved in complement- and cytotoxic T-lymphocyte-mediated cytolysis

Jürg Tschopp*, Danièle Masson* & Keith K. Stanley?

* Institute of Biochemistry, University of Lausanne, CH-1066 Epalinges, Switzerland † EMBL, Meyerhofstrasse 1, Postfach 10.2209, D-6900 Heidelberg, FRG

Cytolysis mediated by complement or cytolytic lymphocytes results in the formation of morphology similar lesions in the target membrane¹⁻⁶. These lesions, formed by the polymerization of C9 or perforin respectively, contribute the major killing action by causing osmotic lysis of the target cell. Following the suggestion of Mayer7 that the mechanisms of humoral and cell-mediated cytotoxicity might be related, studies into the morphology of the membrane lesions formed⁸⁻¹³, and the proteins responsible for causing the lesions^{9,14,15}, have shown several similarities. While the lesion caused by natural and T-killer cells is a little larger than that caused by complement, its overall shape is similar and in both cases the cylindrical pore is formed by polymerization of a monomeric subunit, C9 (relative molecular mass, $M_r = 71,000$) for complement⁹, and perforin $(M_r = 66,000)$ for cell-mediated cytotoxicity^{14,15}. C9 has an absolute requirement for a receptor in the target membrane formed by the earlier membrane attack complex components, C5b, C6, C7 and C8 (ref. 8). For perforin. polymerization in a target membrane requires no receptor, specificity being derived from the specific recognition between killer and target cell. Both proteins can be made to polymerize in vitro by the addition of divalent cations (Zn²⁺ for C9 (ref. 16) and Ca²⁺ for perforin^{10,12,13}) and the resultant complexes closely resemble their physiological counterparts. Antibodies raised

against lymphocyte-killed targets have also been shown to cross-react with complement proteins 17,18,33, but the antigenically related proteins were not determined in these studies. We show here using purified proteins that perforin, C9 and complexes involving C7 and C8 share a common antigenic determinant which is probably involved in polymerization.

During the expression screening of a human cDNA library in pEX (ref. 19) it was noted that one clone, which did not contain C9 sequences, reacted strongly with a polyclonal antibody of high specificity to C9 (clone C9.1 in ref. 19). When the antibody affiinity purified on this fusion protein was tested in Western blots of purified proteins it was found that it bound strongly to mouse perforin. This fusion protein was therefore used to boost rabbits initially injected with mouse perforin.

Figure 1 shows the Western blot analysis using this particular antiserum named C9.1 (Fig. 1a). Not only were purified perforin and C9 immunostained, but a single band appeared with the same apparent M_r as perforin when whole cytoplasmic cytotoxic T-lymphocyte (CTL) granules were analysed. The antiserum did not react with bovine serum albumin or other serum proteins; however, in half of the experiments, C7 was also detected (data not shown).

When a panel of monoclonal antibodies raised against human monomeric C9 was tested, none reacted with mouse perforin, but one monoclonal antibody (BC5), originally described as binding only to epitopes present on poly C9 (ref. 19), did cross-react. This neoantigen-specific antibody binds to a nonconsecutive epitope, and thus binds only weakly to C9 separated in the presence of SDS and transferred to nitrocellulose. In contrast, dot-blot analysis, which presumably conserves this epitope, can be used for its analysis (Fig. 1b). Less than 160 pg of poly-C9 can be immonostained using this antibody, whereas C5b-6, C7, C8 and monomeric C9 do not stain. In contrast, when the late components are first mixed to form the respective complex and then applied to the nitrocellulose, C5b-7, C5b-8, C5b-9 (comprising poly C9) and poly-C9 are all stained. These complexes must therefore exhibit a common epitote not present on the individual precursor proteins.

The amino-acid sequence of C9^{19,20} contains two cysteine-rich regions¹⁹ which show sequence and predicted structural homology²¹ to the low-density lipoprotein (LDL) receptor and urokinase. The function of these regions is unknown, but one hypothesis is that these regions form compact globular domains involved in the polymerization of C9. We therefore postulated that if mouse perforin and human C9 shared a common domain, it was most likely to be found in one of these conserved regions, since both molecules polymerize in a similar manner.

Two peptides were synthesized corresponding to amino acids 74-86 (peptide A) and 101-111 (peptide B) of C9, that is, the segment with high homology to the LDL receptor (Fig. 2). Antibodies raised against the peptides coupled to ovalbumin were tested for their reactivity to C9 and perforin. Both antipeptide A and anti-peptide B immunostained human C9 and mouse perforin (Fig. 3). Perforin staining was considerably weaker, especially when immunoblotting was performed using anti-peptide A. These results suggest that the amino-acid sequence of perforin must be slightly different, especially in segment 74-86 of C9. This second segment also shows a lower degree of homology to the LDL receptor than does the segment corresponding to peptide B. In addition to C9, anti-peptide B bound to $C8\alpha$ (ref. 22), to C7, and weakly to C6. Anti-peptide A also reacted with $C8\alpha$, C7 and C6, although binding to C7 was extremely weak. Other proteins tested, such as bovine serum albumin, were not stained at all with anti-peptide B²² and anti-peptide A (Fig. 3). Binding could also be inhibited by addition of the corresponding peptide. This was true for antibody binding to C9 (Fig. 3), $C8\alpha$ (ref. 22), C7, C6 and perforin (data not shown).

To exclude the possibility that the binding of the anti-peptide entibodies to these proteins was a chance event, the Dayhoff

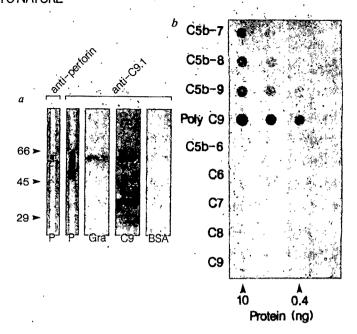

Fig. 1 a, Cross-reactivity of C9 with perforin. Perforin (P), granules (Gra), C9 and bovine serum albumin (BSA) were separated under reducing conditions on a 10% polyacrylamide²⁷ gel in the presence of SDS (SDS-PAGE) and transferred to nitrocellulose²⁸. As a control, perforin was incubated with a specific rabbit anti-perforin antiserum under the same conditions (left panel). b, Dot-blot analysis of complexes of the late components of complement using monoclonal antibody BC5 as a probe.

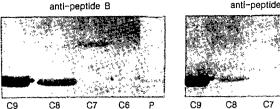

Methods. a, The nitrocellulose membrane was incubated for 2 h in a buffer containing 20 mM Tris-HCl pH 8.4, 150 mM NaCl, 5 mM EDTA, 1% gelatin and 0.1% BSA. Anti-C9.1 antiserum was then added at a 1:100 dilution in the same buffer. The blot was developed with protein-A-peroxidase conjugate using 4-chloro-1-naphthol and H₂O₂ as substrates. Perforin and granules were isolated from the mouse CTL line B6.1 as described elsewhere 12,14. Antibody C9.1 was raised in rabbits by injection of 20 µg purified mouse perforin in Freund's complete adjuvant into popliteal lymph nodes of rabbits followed by three boosts with 20 µg of perforin administered intradermally. Fusion protein from clone C9.1 (ref. 19) was then injected intradermally three times at intervals of 3 weeks and the animal bled 11 days after the final injection. b, Complement proteins C5b-6, C7, C8 and C9 were prepared according to standard procedures²⁹. 10 ng, 2 ng, 0.4 ng, 80 pg of the proteins were adsorbed to nitrocellulose using the dot-blot microfiltration apparatus (BioRad). The different complexes were formed by mixing the respective proteins C5b-6 (1 µg), C7 (0.5 µg), C8 (0.6 µg) and C9 (1.3 µg) in 100 µl Tris-buffered saline (TBS, 10 mM Tris-HCl pH 7.4 containing 150 mM NaCl), incubating them at 20 °C for 15 min (in the case of the C5b-9 complex, incubation temperature was 37 °C). Poly-C9 was formed by incubating 10 µg C9 in 10 µl TBS containing 10⁻⁴ M ZnCl₂ for 2 h at 37 °C. The protein mixtures were diluted to the appropriate concentration and then applied onto the nitrocellulose membrane. Immunostaining was performed as described in a, using a 1/500 dilution of the monoclonal antibody.

Fig. 2 Comparison of the homology regions of C9 and the LDL receptor^{19,24}. The peptides synthesized are indicated in the boxed area.

Methods. Peptides were synthesized according to a modified Merrifield method³⁰, using (fluoroenylmethoxycarbonyl) protected amino acids (Bachem). A semiautomatic peptide syntesizer (Labortec) was used for the synthesis. Peptides were purified on a preparative Mono Q column (Pharmacia, FPLC system).

Fig. 3 Western blot analysis of C6, C7, C8, C9 and perforin (P). Samples of 3 μ g of C6 (M_r 115,000), C7 (M_r 110,000), C8 (C8 α , M_r 68,000, C8 β , M_r 65,000, C8 γ , M_r 15,000), C9 (M_r 71,000) and perforin (M_r 66,000) were separated under reducing conditions by SDS-PAGE and transferred to nitrocellulose²⁸. Antipeptide A antiserum and anti-peptide B antisera were added at a 1:100 dilution. Binding of the antibodies was revealed using protein-Aperoxidase conjugates (1:1,000 dilution,

Sigma). The specificity of anti-peptide A antiserum is shown in the right panel: nitrocellulose-bound C9 was incubated with the antiserum in the presence and absence of 100 μ M peptide A. Blotted BSA incubated with anti-peptide A is shown as an additional control. Antisera to the peptides were raised by injecting 200 μ g of peptides coupled to ovalbumin with bis-diazobenzidine³¹ in complete Freund's adjuvant on day 0. The animals were boosted with the same quantity of peptide in incomplete Freund's adjuvant on days 14 and 28 and were bled on day 35.

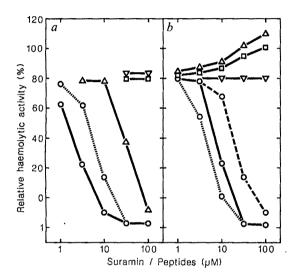

Fig. 4 Effect of peptides and suramin on C7, C8, C9, CTL granule and perforin haemolytic activity. a, Inhibition of perforin (dashed line) and granule activity (solid lines) by peptide A (\square), peptide B (\triangle), a peptide (CDDDPPEIPHAT, ∇) derived from the sequence of the interleukin-2 receptor³² and suramin (\bigcirc) (Bayer, Wupperthal). b, Inhibition of C7 (dashed line), C8 (dotted line) and C9 activity (solid line) with the agents detailed in a.

Methods. Granules (100 µl) isolated from the CTL line B6.1 (ref. 12) or purified perforin¹⁴ were adjusted to a concentration lysing 80% of the sheep red blood cells, and mixed with the peptides/suramin and 300 μ l sheep erythrocytes (1.5 × 10⁷ cells per ml) in a solution containing 10 mM Veronal buffer pH 7.4, 142 mM NaCl, 0.1% gelatin, 1 mM Ca²⁺ and 0.15 mM Mg²⁺ (GVB). The mixture was incubated for 15 min at 37 °C, the erythrocytes spun down at 1,500 r.p.m. for 5 min, and the degree of haemolysis measured by determining the haemoglobin release at 412 nm in a Gilford spectrophotometer. The haemolytic activity was calculated as Z number ¹³. The decrease in the Z number was then transformed into relative haemolytic activity. b, C9 haemolytic test9 was performed by diluting C9 to a concentration causing 80% lysis of the erythrocytes (usually 1-2 ng ml⁻¹). C9, inhibitors and erythrocytes bearing complement components C1-C8 on their surface (1.5× 10⁷ cells per ml) were then mixed in a total volume of 400 µl GVB and incubated for 30 min at 37 °C. The degree of lysis was determined as outlined above. C8 activity²² was carried out by incubating erythrocytes having C1 to C7 bound $(1.5 \times 10^7 \text{ cells per ml})$ with inhibitors and 0.1 µg ml⁻¹ C8 for 15 min at 37 °C in 400 µl GVB. The cells were washed twice in GVB and resuspended in 400 μl GVB containing 1 μg ml⁻¹ C9. Incubation was continued for 30 min at 37 °C and the degree of haemoglobin release determined. C7 activity was determined accordingly with C1-C6 bearing erythrocytes. The inhibitors were added with C7 (0.1 µg ml⁻¹) and after washing, excess of C8 and C9 was added. C6 activity could not be determined, since erythrocytes carrying C1-C5b lose C6 binding activity instantaneously.

protein sequence data bank was scrutinized for the presence of one of the sequences corresponding to the C9-derived peptides. Using the MATCH routine of the Protein Identification Resource²³, we searched for proteins having 6 out of the 11-13 amino acids of peptide A or peptide B in common on the assumption that 6 amino acids are sufficient for an antigenic site. Seven proteins (including the LDL receptor) fulfilled this criterion for peptide B and 15 proteins for peptide A. However, only C9 showed up in both searches, indicating the low probability that a random protein could be detected by the two antipeptide antibodies.

The above results thus suggest that C6, C7, C8 α , C9 and perforin all contain structures homologous to the aminoterminal cysteine-rich region of the LDL receptor. In the LDL receptor, this region binds to the LDL apoprotein B²⁴ in a manner inhibited by two negatively charged molecules, suramin²⁵ and heparin²⁶, suggesting an electrostatic interaction with its ligand. Since a similar interaction within the C9 molecule might account for its polymerization, we tested suramin and the peptides A and B for a direct effect on cytolysis. Figure 4 shows that both C9 and perforin activity were completely abrogated at concentrations above 30 μ M and 10 μ M suramin, respectively. A twofold higher concentration was required for the suppression of perforin activity when perforin was present in CTL granules. C7 and C8 activity were suppressed over a similar range of concentrations.

When the peptides themselves were tested for their inhibitory action, peptide B was found to inhibit granule-mediated cytolysis at concentrations above $100~\mu\text{M}$, but C9 activity was unexpectedly enhanced. At $100~\mu\text{M}$ peptide concentration, C9 activity was augmented 1.3-fold. The same enhancing effect on C9 activity was observed when peptide A was tested, although this peptide did not affect granule or perforin activity (Fig. 4). As a control, a peptide derived from the interleukin-2 receptor showed no effect at all.

We have shown that C9 and perforin contain one or more similar antigenic determinants which cross-react with antibodies raised against intact proteins and synthetic peptides. One of these similar antigenic regions is located in the segment of C9 bearing homology to the LDL receptor. The ability of suramin to inhibit cytolytic activity of C9 suggests that the negatively charged region of the LDL receptor homology region is involved in C9 polymerization. Peptide B, which encompasses this negatively charged region, has opposite effects on perforin and C9 activity. This is particularly interesting because C5b8 complexes, which are essential components in a target membrane for C9 activity, also contain a determinant antigenically related to peptide B. It is possible therefore that the potentiation of C9 activity in the presence of peptide B is also a reflection of the catalytic activity of C5b8.

We thank Dr H. Haymerle and Dr E. Mollnes for antisera, E. Burnier, R. Etges and Z. Freiwald for help in preparing the manuscript, and Ch. Estrade and S. Schäfer for technical assistance. J.T. is supported by a grant of the Swiss NSF.

Probing the phagolysosomal environment of human macrophages with a Ca²⁺-responsive operon fusion in Yersinia pestis

Charles Pollack*, Susan C. Straley† & Mark S. Klempner*‡

* Department of Medicine, Tufts University School of Medicine, New England Medical Center, Boston, Massachusetts 02111, USA † Department of Medical Microbiology and Immunology, Albert B. Chandler Medical Center, University of Kentucky, Lexington, Kentucky 40536, USA

Several microorganisms, including Yersinia sp., Salmonella sp., Brucella sp., Mycobacterium sp. and Leishmania sp., have successfully adapted to grow within macrophage phagolysosomes. Infections caused by these intracellular pathogens are among the most difficult to treat. As part of an antimicrobial strategy directed at modifying the phagolysosomal environment to the disadvantage of these important pathogens, we are defining the ambient conditions within the organism-containing phagolysosome. To probe this environment, we have used Yersinia pestis, whose expression of several virulence attributes is highly dependent on the Ca2 concentration in its growth environment. We first genetically engineered a strain of Y. pestis which responds to a low-calcium environment by transcription of inserted structural genes of the Escherichia coli lac operon. Using this mutant organism as a relevant biological probe, we demonstrate here that the calcium concentration in Y. pestis-containing phagolysosomes is sufficiently low to permit virulence gene expression; this resolves the question of where Y. pestis might express its Ca2+-regulated genes in vivo.

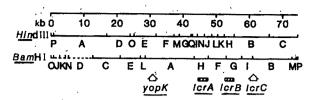

Fig. 1 Location of the mutation used in the present study within the physical map of pCD1. The site of the insertion mutation (yopK) is indicated for the BamHI and HindIII restriction maps of pCD1. Also shown are the locations of low-Ca2+-response (lcr) genes necessary for the growth requirement for Ca²⁺ at 37 °C and for high expression of the V antigen. Broken lines indicate sections where the restriction fragment order is uncertain.

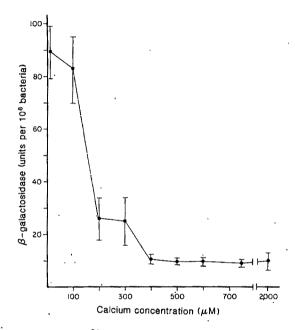

Fig. 2 Effect of Ca^{2+} on β -galactosidase production by Y. pestis KIM6 (pCD1:: Mu dI1-31): The enzyme activity is expressed as a function of the number of bacteria, as determined by counting in a Petroff-Hausser chamber under a microscope. One unit of β -galactosidase activity is equal to 10 μ mol of p-nitrophenyl cleaved from the substrate p-nitrophenyl-D-galactopyranoside, per min, measured over a 12-h period. Each point represents the mean ±s.e.m. of 4-11 separate experiments, each run in duplicate. Methods. Y. pestis KIM6 (pCD1:: Mu dI1-31), which had been maintained at 26 °C, was grown at 37 °C in heart infusion broth supplemented with 0.2% xylose, 2 mM MgCl₂ pH 7.0, at the indicated free Ca²⁺ concentration. The free Ca²⁺ concentration of solutions was calculated from the contaminating Ca²⁺, measured with a Ca²⁺-sensitive electrode (model F2112, Radiometer, Inc., Copenhagen, Denmark), and the amount of Ca2+ added. After 8 h exponential growth, the bacteria were lysed with SDS/chloroform and β -galactosidase production was measured at pH 8.0 according to the method of Conchie et al.12.

Y. pestis, the bacterium which causes plague, is a facultative intracellular organism which grows and multiplies in phagolysosomes within macrophages of the mammalian reticuloendothelial system¹. At least five virulence determinants have been identified for Y: pestis²; one of the most important of these is the response to low Ca²⁺, which is manifested as two coordinately expressed properties: the requirement for millimolar Ca2+ for growth at 37 °C and the ability to synthesize a set of virulenceassociated proteins, including the plague virulence antigens V and W (Vwa⁺ or Lcr⁺ phenotype)^{3,4}. While the precise functions of these proteins are unknown, mutational loss of the ability to express them results in loss of virulence. For example, the mouse

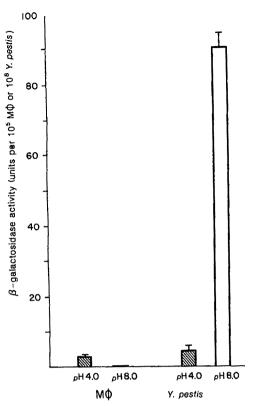

Fig. 3 Effect of pH on β-galactosidase activity of human macrophages and Y. pestis KIM6 (pCD1::Mu dI1-31).

Methods. Y. pestis KIM6 (pCD1::Mu dI1-31) was grown in the presence of 1.0 μM Ca²⁺, as described in Fig. 2 legend. Human mononuclear cells were isolated from heparinized peripheral blood from healthy volunteers and cultured for 24 h in RPMI 1640 tissue culture medium supplemented with 10% fetal calf serum (FCS)¹³. All cells were lysed with SDS/chloroform, as described by Miller¹⁴, and β-galactosidase activity was measured as described by Conchie et al. ¹² at pH 4.0 or pH 8.0. β-galactosidase activity is expressed in units (see Fig. 2).

LD₅₀ (50% lethal dose) for subcutaneously or intravenously injected Lcr+ Y. pestis is less than 10 bacteria, but >107 bacteria for Lcr Y. pestis. At 37 °C the expression of V and W antigens by Y. pestis is closely controlled by the calcium concentration in the growth environment, that is, the coordinated induction of these virulence proteins occurs only when the ambient calcium concentration is in the submillimolar range, well below the extracellular calcium concentration of the human host. Therefore, in order to express V and W antigens and remain virulent, Y. pestis must inhabit an intracellular environment with a low toncentration. The unusual sensitivity of this organism to ambient calcium provides an opportunity to gain information about the phagolysosomal Ca²⁺ concentration. As precise measurement of V and W antigens is cumbersome, we have exploited an insertion mutant of the pCD1 plasmid which encodes the low-Ca2+ response, Y. pestis KIM6 [pCD1:: Mu dI1(Ap lac)::Tn9-31], hereafter called Y. pestis KIM6 (pCD1:: Mu dI1-31)5.

This mutant contains an insertion of the transposing operon fusion bacteriophage Mu dI1(Ap lac)⁶ that eliminates expression of YopK, an outer membrane protein necessary for virulence of Y. pestis⁵ (Fig. 1). The insertion does not affect the expression of V antigen or the growth requirement for Ca^{2+} at 37 °C (ref. 5). The insertion was stabilized against additional transposition or induction of phage functions by the presence of Tn9 in the Mu B gene⁵. Mu dI1(Ap lac) contains the structural genes of the E. coli lac operon, which are expressed as a result of readthrough from the yopK promoter. Y. pestis normally is lac^- ; accordingly, expression of the lacZ gene product, β -galac-

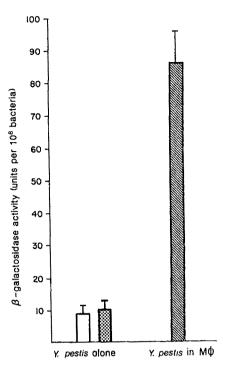

Fig. 4 β -Galactosidase production by extracellular Y. pestis recovered from dishes either without (open bar) or with (stippled bar) macrophages compared with β -galactosidase production by macrophage-associated Y. pestis (hatched bar). β -Galactosidase activity was assayed at pH 8.0 and is expressed as in Fig. 2. Results are the mean \pm s.e.m. of five separate experiments each run in duplicate.

Methods. Y. pestis KIM6 (pCD1:: Mu dI1-31), which had been grown at 37 °C in supplemented heart infusion broth containing 2.0 mM Ca2+ (ref. 1), were washed and resuspended in Hank's balanced salts solution (HBSS) containing 1.0 mM Ca2+ Mg²⁺ and 10% FCS, pH 7.4. The bacterial suspension (10⁸ organisms) was added to Petri dishes in the absence or presence of a monolayer of human macrophages. The macrophage monolayers had been cultured at 37 °C in a humidified atmosphere of 95% air/5% CO₂ in RPMI-1640 medium plus 10% FCS for 24 h, and then washed with HBSS (as above) before addition of the bacterial suspension. In those dishes containing macrophages, the final ratio of bacteria to macrophages was ~10:1. After 8 h of incubation at 37 °C, extracellular Y. pestis were recovered by decanting the dishes, and the organisms were counted in a Petroff-Hausser chamber. The dishes with a macrophage monolayer were gently washed with prewarmed (37 °C) HBSS (1.0 mM Ca+, pH 7.4), leaving behind adherent macrophages containing intracellular and tightly attached Y. pestis. The cells were dislodged with a rubber policeman, counted in a haemocytometer and using an electronic particle counter (Coulter), and macrophage-associated Y. pestis were counted using the fluorescent acridine orange staining procedure of Bertalanffy et al.15.

tosidase, provides a measure of the transcription of yopK. Even though yopK is distant from the lcr genes (Fig. 1) and the V gene (S.C.S., unpublished), it shows the same pattern of expression as V antigen in yersiniae grown under different conditions⁵

Figure 2 shows that the synthesis of β -galactosidase by Y. pestis KIM6 (pCD1::Mu dI1-31) is strictly controlled by the environmental calcium concentration. When grown at calcium concentrations between 400 and 2,000 μ M, a condition in which Lcr⁺ Y. pestis expresses V and W antigens only weakly, β -galactosidase production was suppressed. In growth media with a calcium concentration of 200-300 μ M, there was a small increase in β -galactosidase production. In contrast, ambient calcium concentrations between 1 and 100 μ M induced maximal expression of β -galactosidase.

As our goal was to use bacterial β -galactosidase activity as an indicator of the phagolysosomal calcium concentration, it was important to distinguish between the B-galactosidase activity of the macrophage and that of Y. pestis; we therefore examined the pH optima for expression of macrophage and mutant Y. pestis β -galactosidase activity (Fig. 3). β -Galactosidase from disrupted macrophages was almost undetectable at pH 8.0, but fully active at pH 4.0. In contrast, β -galactosidase produced by the mutant Y. pestis grown in a low-calcium (1.0 µM) environment was highly active at pH 8.0; at pH 4.0, less than 10% of the microbial β -galactosidase activity was

Figure 4 compares β -galactosidase activity of extracellular mutant Y. pestis with that of organisms contained within human macrophages. In media containing 1 mM calcium, extracellular Y. pestis which had never been exposed to the macrophages produced little β -galactosidase. Similarly, extracellular Y. pestis recovered from the supernatant of dishes containing infected macrophages also produced little β -galactosidase. In contrast, the mutant Y. pestis contained within the human macrophages produced large quantities of β -galactosidase.

These studies, in which we used a genetically engineered intracellular pathogen to elucidate the environmental conditions in which it grows and multiplies in vivo, demonstrate that the intraphagolysosomal calcium concentration surrounding Y. pestis is sufficiently low to promote expression of calcium-sensitive virulence genes. We hypothesize that those genes encoding V antigen and outer membrane proteins are expressed during intraphagolysosomal growth of this pathogen; this was not expected, because it has been assumed that the Y. pestiscontaining phagolysosome contains millimolar levels of free Ca²⁺ (ref. 1). Based on our data (Fig. 2), we predict that the intraphagolysosomal calcium concentration is <100 µM. This is a surprising result in view of recent descriptions of ATP-dependent Ca²⁺ translocating pumps located in the plasma membrane of macrophages⁸ and neutrophils⁹ as well as a similar Ca²⁺ uptake pump in neutrophil lysosomes¹⁰. If the portion of the phagocyte plasma membrane which formed the phagocytic vacuole contained Ca2+ pumping activity and fused with lysosomes containing a similar Ca2+ pump, both of these ion translocating pumps would tend to raise the calcium concentration within this compartment. The consequences to intracellular Y. pestis would be the inability to express certain virulence genes and the organism would then be eradicated. It remains to be determined whether the calcium concentration is generally low in this intracellular compartment or whether Y. pestis, like Toxoplasma gondii11, can modify its ambient growth environment to its own advantage.

We thank Robert Gelfand for technical assistance and Ms Debra Becky and Ms Carol McClarey for preparation of the manuscript. These studies were supported by NIH grants AI16732 and AI21017.

Diversity of murine gamma genes and expression in fetal and adult T lymphocytes

Joseph S. Heilig & Susumu Tonegawa

Center for Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

The search for the genes encoding the T-cell receptor α and β chains revealed a third gene, Ty (ref. 1), which shares with the $T\alpha$ (refs 2-7) and $T\beta$ (refs 8-15) genes a number of structural features, including somatic rearrangement during T-cell development. Ty gene expression appears to be unnecessary in some mature T cells^{16,17} and is at its greatest in fetal thymocytes^{18,19} encouraging speculation that $T\gamma$ has a role in T-cell development and may be involved in the recognition of polymorphic major histocompatibility complex (MHC) products during thymic education^{20,21}. One argument against the participation of $T\gamma$ in such a process has been its apparently limited diversity, due to the small number of gene segments available for rearrangement^{1,22}. We here describe the identification of additional Ty V-gene segments and demonstrate that they can be rearranged to previously identified J- and C-gene segments and are expressed in fetal thymocytes. In addition we describe a variety of patterns of Ty mRNA processing which may be significant for Ty gene regulation.

Previous studies^{1,22} identified three cross-hybridizing mouse V_{γ} -gene segments, V_1 , V_2 and V_3 , and three sets of crosshybridizing J_{γ} - and C_{γ} -gene segments, J_1 - C_1 , J_2 - C_2 and J_3 - C_3 (see ref. 23 for nomenclature). Recently Iwamoto and coworkers²⁴ have reported a fourth set of J and C segments, J_4 - C_4 , which does not cross-hybridize with the other three (see Fig. 3). Although none of these germline gene segments have (with possible exception of C_3) obvious structural defects only the V_2 - J_2 - C_2 combination has been found as a complete rearranged gene^{1,16}. However, the existence of additional germline V_{γ} -gene segments, which do not cross-hybridize to the first three \dot{V} -gene segments and are also rearranged in T cells, is suggested by two observations. First, many T-cell clones and splenic and peripheral T cells carry, in addition to a joined V_2 - J_2 - C_2 gene, an EcoRI DNA fragment containing a rearranged J_1 - C_1 segment^{1,16,17,22}. Second, fetal thymocytes seem to contain more transcripts hybridizing to a C_{γ} -probe which detects C_1 , C_2 and C_3 sequences than to a V_2 -probe which detects V_1 , V_2 and V_3 sequences18.

To confirm this suspicion we constructed a cDNA library from fetal thymocytes and isolated cDNA clones which hybridize to a C_{γ} -probe but not to a V_{γ} -probe. Sequence analysis of one of these clones (FT2) revealed a new V_{γ} -gene segment (V_4) which shares 50% amino acid sequence homology with V_2 and is rearranged to the J_1 - C_1 gene segment (Fig. 1). As is often the case with $T\gamma$ -gene transcripts^{1,16,23,25} the V_4 - J_1 joint in FT2 results in a frame shift such that a translation product would terminate in the J region. Another clone, FT6, contains part of the sequence of another V_{γ} -gene segment (V_5) which is also rearranged to J_1 - C_1 (Fig. 1). Although the complete sequence of V_5 was not contained in this clone, sufficient sequence was obtained to distinguish it from other V-gene segments. The V_5 - J_1 joint in FT6 would also result in premature termination of translation. Nevertheless these new V_{γ} -gene segments indicate

the potential of additional variability in the γ -gene family. Figure 2 shows the result of a Southern blot analysis²⁶ in which DNA from a variety of T-cell clones and a 17-day-old fetal thymocyte population was analysed using C_2 -, V_2 -, V_4 and V_5 -probes in panels a, b, c and d, respectively. The C_2 probe detects C_1 , C_2 and C_3 ; the V_2 -probe V_1 , V_2 and V_3 . The characteristic pattern of double rearrangement with C_2 and

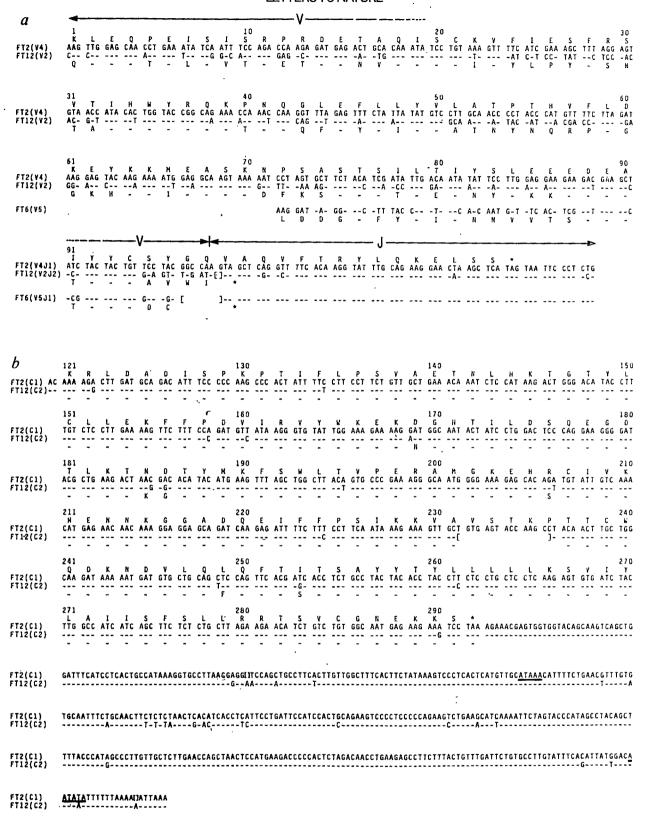

Fig. 1 The nucleotide sequences of $T\gamma$ -cDNA clones. a, the V- and J-region sequences of three cDNA clones. FT2 (V_4 - J_1 - C_1), FT12 (V_2 - J_2 - C_2) and FT6 (V_5 - J_1 - C_1). b, C_1 sequence, determined by analysing clone FT2, compared with C_2 sequence from FT12. The predicted amino acid sequences are indicated by the single-letter code. Dashes indicate sequence identity to that of FT2; parentheses enclose gaps necessary to align the sequences. The underlined regions in b indicate polyadenylation signals.

Methods. Pregnant BALB/cByJ mice at day 17 of gestation were killed and the fetuses removed. Thymuses of 82 fetuses were pooled and disrupted by gentle homogenization in a ground-glass tissue grinder. The thymocytes were collected and washed twice in cold phosphate buffered saline (PBS) and RNA was prepared by the guanidinium/CscI method³⁴. Poly(A)⁺ RNA was isolated³⁵ and used as a template for cDNA synthesis³⁶ and the resulting double-stranded DNA was cloned into λ gt10 by standard procedures³⁷. All sequences were determined by the method of Maxam and Gilbert³⁸.

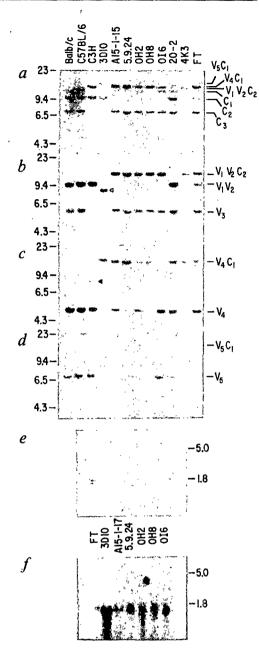

Fig. 2 Southern²⁶ and Northern³⁹ blot analyses of T-cell lines and fetal thymocytes. Panels a-d show Southern blot data while panels e and f show Northern blot data. In the Southern blots, BALB/c, C57BL/6 and C3H indicate kidney DNA of the designated strains; FT, DNA or RNA from 17-day-old BALB/c fetal thymocytes; 3D10, a KLH-specific suppressor T-cell line from C3H⁴⁰; A15-1-17, an alloreactive anti-I-A^k cytolytic T-cell line from A.TH⁴¹; 5-9-24, an I-A^d- ovalbumin-specific cytolytic/helper T-cell line from BALB/c (gift of B. Jones and C. Janeway); OH-2 and OH-8, Db- H-Y-specific cytolytic T-cell lines from C57B/6 (gift of O. Kanagawa); OI-6, an I-Ab H-Y- specific helper T-cell line from C57BL/6 (gift of O. Kanagawa); 20.2, an anti-H-2^b alloreactive helper T-cells line from BALB/c¹⁶; 4K3, an anti-L^d alloreactive cytolytic T-cell line from BALB.K²³. The unrearranged and rearranged gene segments are identified on the right hand side of panels a-d. The arrow in b indicates a V_2 -cross-hybridizing band rearranged to unidentified sequence; probably an example of V_1 - J_4 - C_4 rearrangement (see Fig. 3 and ref. 24). The arrow in c indicates a V₄ crosshybridizing band which may indicate partial digestion of the C3H kidney DNA.

Methods. In the Southern blot analysis, DNA samples were digested with EcoRI. Approximately 2 μ g of each sample was electrophoresed in a 0.8% agarose gel, transferred to nitrocellulose and hybridized by standard procedures⁴². For the Northern blot analysis, RNA was prepared by the guanidinium/CsCl method³⁴ and approximately 12 μ g of each sample was electrophoresed, transferred to nitrocellulose and hybridized as previously described^{17,39,42}. Probes used are: (a), the DNA encoding nearly the entire C_2 region depicted in Fig. 1b (detects C_1 , C_2 and C_3); b, f, the region encoding the first 100 amino acids of V_2 (Fig. 1a) (detects V_1 , V_2 and V_3); c, e, the region encoding the first 78 amino acids of V_4 (Fig. 1a); d, V_5 as described below. C_2 , V_2 and V_4 probes were labelled by nick translation⁴³. Filters hybridized with these probes were washed in 0.4 × SSC/0.1% SDS at 65 °C. The V_5 probe was prepared and used as follows. A synthetic oligonucleotide corresponding to the 76 nucleotides of V_5 (Fig. 1a) was prepared and purified as described⁴⁴. A sesquidecamer complementary to the 3' end of this sequence (5' GCAGGCACAGTAGTA 3') was also synthesized. The probe was radiolabelled by a modification of the primer extension method⁴⁵. Hybridization was carried out at 55 °C. Filters were washed in $2 \times SSC/0.1\%$ SDS at 55 °C and exposed to film.

 C_1 previously reported^{1,16} can be seen in most of these cells. In 20-2 however only C_1 rearrangement has occurred and in OI-6 only C_2 rearrangement. In cells containing a rearranged C_1 segment, the V₄ segment always rearranged to the same EcoRI fragment (Fig. 2a, c). The same correlation applies to C_2 - and V_2 -segments (Fig. 2a, b). By contrast, despite its rearrangement to the J_1 - C_1 segment in the 17-day-old thymocytes, as evidenced by the Southern blots (Fig. 2a, d) and the isolation of the FT6 cDNA clone (Fig. 1), V_5 is not rearranged in any of the T-cell clones studied. Instead, V_5 is present only in those T-cell clones that retain at least one copy of unrearranged V_4 - and C_1 segments, suggesting that rearrangement of V_4 to J_1 - C_1 results in deletion of V_5 . When these DNA samples are hybridized with a probe detecting a part of the C_4 gene, rearrangement is seen only in 3D10 DNA (data not shown, but apparently the same band as the one indicated by the arrow in Fig. 2b) which suggests that the $V_1J_4C_4$ rearrangement reported by Iwamoto and coworkers²⁴ is not very frequent among T-cell clones. The most probable organization of the various γ -gene segments, on the basis of all available data, is shown in Fig. 3.

The level of RNA containing V_2 - or V_4 -sequences was examined in 17-day-old fetal thymocytes as well as in a variety

of T-cell clones (Fig. 2e, f). All cells examined contained V_2 RNA. By contrast only fetal thymocytes contained V_4 RNA. Further analysis by cDNA cloning and sequencing revealed that most of the y RNA in 17-day-old fetal thymocytes, whether of the V_2 - J_2 - C_2 , V_4 - J_1 - C_1 or V_5 - J_1 - C_1 type, is apparently nonfunctional because of out-of-frame V-J junctions. Of eight cDNA clones sequenced which contain a rearranged V_2 -, V_4 - or V_5 segment, all had out-of-frame V-J junctions (see Fig. 1a, clones FT2, FT12 and FT6). Furthermore, many of these cDNA clones use splice sites other than those used in generating normal γ mRNA. Thus, as shown in Fig. 4, clone FT11 uses a splice acceptor in what is normally the V_2 coding region, clone FT6 employs a splice acceptor in what is normally the J_1 - C_1 intron and clone FT5 uses the same acceptor and a splice donor also in the J_1 - C_1 intron. In addition, clone FT10 presumably resulted from transcription initiating upstream of an unrearranged J2gene segment and clone FT13 uses an alternate polyadenylation site.

This study has added two V_{γ} - gene segments, V_4 and V_5 , to the previously recognized sets of three V- and four J-C-gene segments. We now have evidence for rearrangement and expression at the RNA level of at least three types of $T\gamma$ genes,

Fig. 3 The arrangement of the γ genes, inferred from all available data. The orientation of the three gene clusters with respect to one another has not yet been determined. The broken line indicates the J_4 - C_4 cluster described elsewhere²⁴.

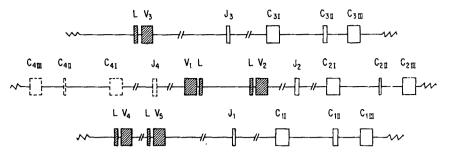

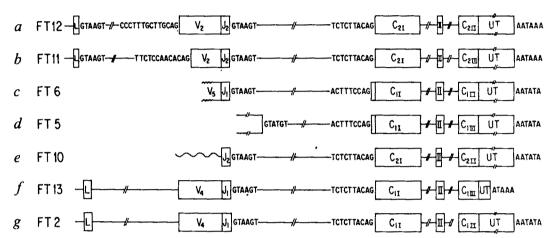

Fig. 4 Alternate splice patterns of y-gene transcripts. Several types of mRNA generated by use of different splice signals are shown schematically. The boxed regions indicate exons and are labelled when the identity is known. The leader region is indicated by L; the first, second and third exons of the C regions by I, II and III respectively; the untranslated regions by UT. Straight lines represent introns and are flanked by the nucleo-

tide sequences of the splice signals. Only the sequences of relevant splice signals are indicated. In clone FT10 the wavy line indicates chromosomal sequence 5' of I2. The nucleotide sequence to the right of the UT region is the polyadenylation signal⁴⁶ presumed to be used by that clone. The normal splice patterns are depicted by clones FT12 and FT2. In clone FT6 the novel splice acceptor is 13 nucleotides upstream of the C_{11} exon. In clone FT5 a splice donor in the J_1C_1 intron 248 nucleotides 5' of C_{11} is used, as the acceptor described for clone FT6. The polyadenylation signals are underlined in Fig. 1b. We sequenced ten cDNA clones, two examples each of types a, b and g and one each of c, d, e and f. In each of the eight cDNA clones containing a V-J junction (FT5 and FT10 do not) the sequence at the V-J junction was different and resulted in frame shift. Splice signals were deduced by comparison to the consensus sequences suggested in ref. 47.

 V_2 - J_2 - C_2 , V_4 - J_1 - C_1 and V_5 - J_1 - C_1 . Within each type there exists sequence variability in the V-J junction (this study and refs 16, 17, 23), indicating that the structural diversity of the Tγ-gene products is not as limited as previously thought. Additional Ty-gene segments may exist which do not hybridize with the available γ probes. In humans, at least two C_{γ} - and six V_{γ} -gene segments have been identified 27,28. The expanded T_{γ} -gene diversity and the structural similarity of this gene to the T_{α} and T_{β} genes support the idea that the role of the Ty gene is in the recognition of polymorphic determinants on target cells. RNA transcripts detected by a C_2 or V_2 probe accumulate in the fetal thymocyte population, which is relatively rich in immature T cells, and are barely detectable in the resting T-cell population obtained from adult lymph nodes 18,19 , suggesting that the $V_2J_2C_2$ gene product is involved in the early development of T cells, perhaps in the interaction with the polymophic MHC determinants presented to immature T cells by thymic epithelial cells^{29,30}. The present finding that V_4 - J_1 - C_1 and V_5 - J_1 - C_1 transcripts are present in fetal thymocytes but not in a variety of T-cell clones supports this hypothesis. However, the fourth $T\gamma$ gene, V_1 - J_4 - C_4 , does not appear to be used abundantly in 17 day-old fetal thymocytes preferentially because it is not represented in our cDNA library, as shown by the fact that all clones hybridizing to a V_2 - probe also hybridize to a C_1 probe $(V_2 \text{ and } V_1 \text{ cross hybridize}).$

The present study shows that most of the Ty RNA present in 17-day-old fetal thymocytes is defective due to out-of-frame V-J joining and abnormal splicing. Examples of out-of-frame joining and abnormal splicing of T-cell-receptor genes have been reported^{4,17,25}. However, the strong bias in favour of presumably nonfunctional mRNA for Ty is striking. Since it is difficult to imagine that in-frame V-J joining is specifically suppressed, the high incidence of out-of-frame cDNA may reflect an aspect of regulation of $T\gamma$ -gene expression. It is possible that the γ protein is required only during an early phase of T-cell development and its continued presence is detrimental to the cell. If so, T cells will be more tolerant to continued transcription of an out-of-frame T_γ gene than an in-frame gene. The implication of this view is that the 17-day-old fetal thymocyte population is dominated by immature T cells that have already passed through the stage in which the Ty gene plays a critical role. Alternatively, the functional expression of the T, gene is restricted to a small fraction of thymocytes destined to become a subset of T-cells as yet unidentified. The significance of the high incidence of apparently abnormal RNA splicing is unclear but may also reflect the need to eliminate in-frame Ty gene products once the cell has passed a critical stage in development. Precedents exist in the literature for the role of alternative splicing in the inactivation of a gene function during viral and cellular development³¹⁻³³

A novel $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joining mechanism in heavy-chain-negative (null) pre-B cells results in heavy-chain production

Michael Reth, Peter Gehrmann, Eva Petrac & Petra Wiese

Institute for Genetics, University of Cologne, Weyertal 121, D-5000 Köln 41, FRG

During B-cell development, the $V_{\rm rf}$ genes of immunoglobulin heavy (H) chains are assembled from three different germline components: the variable (V_H) segment, the diversity (D) segment and the joining (J_H) segment^{1,2}. The joining between two segments involves the recognition of conserved nonamer-heptamer sequences bordering each segment, double-stranded cuts at the heptamersegment border, and the re-ligation of the two segment ends which have frequently been modified by the deletion and addition of nucleotides³⁻⁶. The flexibility of the joint increases $V_H DJ_H$ variability. However, it also results in many pre-B cells which do not produce immunoglobulin H chains and have non-functional $V_{\rm H}DJ_{\rm H}$ complexes carrying the $V_{\rm H}$ and $J_{\rm H}$ coding sequences in different reading frames? We show here that such 'null cells' are not dead-end products of the B-cell developmental pathway but can perform a novel V_H to $V_H DJ_H$ joining using a 5' V_H segment to replace the $V_{
m H}$ sequence of the $V_{
m H}DJ_{
m H}^-$ complex. This process can result in the generation of a $V_H DJ_H^+$ complex and the subsequent expression of an immunoglobulin heavy chain.

In the past we have studied the order and control of immunoglobulin gene rearrangements in the Abelson pre-B-cell line 300-19 (refs 8-11) derived from the bone marrow of an outbreed NIH/Swiss mouse¹². 300-19 cells which originally carry a DJ_H3 complex on each J_H allele⁸ undergo D to J_H and and $V_{\rm H}$ to $DJ_{\rm H}$ assembly while growing in culture. Approximately 30% of the V_H to DJ_H joints of 300-19 place the V_H and $J_{\rm H}$ coding sequence in the same reading frame thus resulting in the production of a μ -chain⁹, the first H chain class expressed in pre-B cells. Many of the 300-19 subclones, however, contain $V_{\rm H}DJ_{\rm H}^{-}$ complexes and fail to produce a μ -chain. To study the fate of such null cells, we analysed P17 and Pa2-5, two isolates of 300-19 carrying unproductive $V_H DJ_H$ complexes.

Aberrant V_H to DJ_H joints had obviously occurred on both $J_{\rm H}$ alleles of P17 because we could not detect any μ -chains nor 5' D sequences in P17 (data not shown). Indeed, all 5' D sequences are generally deleted during the V_H to DJ_H joint of a $J_{\rm H}$ allele³. To our surprise, P17 became more and more μ -

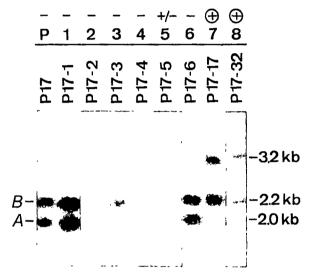

Fig. 1 $J_{\rm H}$ rearrangement in subclones of P17. The two parental $V_{\rm H}DJ_{\rm H}$ alleles of P17 are labelled A and B. Approximately 10 μ g of genomic DNA of the different subclones was digested with EcoRI, electrophoresed through 1% agarose, blotted onto nitrocellulose and assayed for hybridization to a 32 P-lablled $J_{\rm H}$ probe as described previously 3,8 . μ Production in the subclones was determined by Western blotting (see Fig. 2) and is indicated by + or -.

positive over a 3-4 week culture period. After 4 weeks of culture we subcloned P17 by limiting dilution and analysed μ production and J_H rearrangement of isolated subclones. Of 55 P17 subclones analysed, 8 (15%) were found strongly μ -positive in a Western dot assay (data not shown). On a Southern blot the two $V_H DJ_H^-$ alleles of P17 (A and B) are visible as J_H -positive EcoRI fragments of 2 and 2.2 kilobases (kb) respectively (Fig. 1, lane P). In the μ -positive subclones P17-17 and P17-32, the 2-kb EcoRI fragment of the P17-A allele had undergone rearrangement and appeared in a new J_H-positive EcoRI fragment of 3.2 kb (Fig. 1, lanes 7, 8). Three of the six randomly picked subclones had deleted the 2-kb EcoRI fragment (Fig. 1, lanes 2-4). Another of these subclones (P17-5) with weak μ expression (data not shown) showed a faint band of 3.2 kb (Fig. 1, lane 5), suggesting that part of the P17-5 culture was undergoing the same rearrangement event as that occcurring in P17-17 and P17-32. The 2.2-kb EcoRI fragment of the P17-B allele stayed unchanged in all P17 subclones. Thus only the $V_H DJ_H$ complex of the \tilde{A} allele of P17 had undergone genetic alterations. These were either its complete deletion or a further rearrangement correlated with μ production.

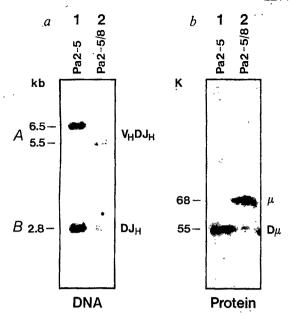

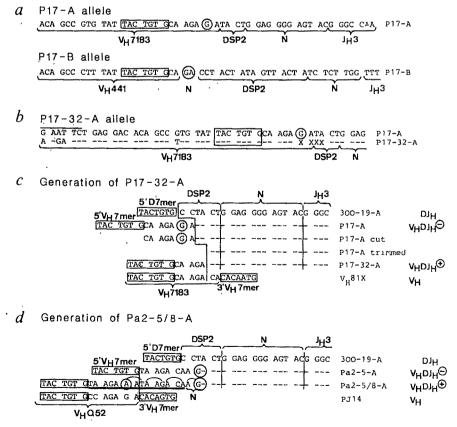

Fig. 2 $J_{\rm H}$ rearrangement and μ production in subclones Pa2-5 and Pa2-5/8. a, Approximately 10 $\mu{\rm g}$ of genomic DNA was double digested with $Bam{\rm HI}$ and $Eco{\rm RI}$ and probed for hybridization with a $J_{\rm H}$ pobe as described previously 3,8 . The position of the two $J_{\rm H}$ alleles is indicated by A and B. b, Intracellular protein of 10^7 cells of each subclone was fractionated by electrophoresis through 10% polyacrylamide gels and electrotransferred to nitrocellulose. Bound μ protein was detected by $^{125}{\rm I}$ -labelled antibodies as described previously 3 .

Fig. 3 Nucleotide sequence of $V_{\rm H}$ to $DJ_{\rm H}$ and $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ rearrangements in 300-19 subclones. The heptamer recognition sequence is boxed. Sequences derived from VH, D, N and $J_{
m H}$ 3 are labelled accordingly. The $V_{
m H}$ sequences are given the names of their respective Vh family as described by Brodeur and Riblet 13,14. Circled nucleotides mark the position where the V_H and DJ_H reading frames are not matched (out of phase). a, Sequence of the two $V_HDJ_H^$ alleles (A and B) of P17. b, Comparison of the P17-32-A sequence with that of P17-A. The P17-A sequence is given and the identity of the P17-32-A sequence is indicated by a dash. Nucleotide deletions in the P17-32-A sequence are indicated by crosses. An internal EcoRI site in the $V_{\rm H}$ sequence of P17-A is overlined, indicating the position up to which both sequences could be compared. c, Generation of P17-32. The sequence of the 300-19 $DJ_{\rm H}3$ A allele8 is given in the first line and the remaining $D-N-J_H3$ sequence in the V_HDJ_H3 complexes is indicated by dashes. All $V_{\rm H}$ sequences are shown up to the border of the internal $V_{\rm H}$ heptamer. The $V_{\rm H}$ sequence of P17-32-A is compared with that of $V_{\rm H}81{\rm X}$ (ref. 41) a germline $V_{\rm H}$ element of the $V_{\rm H}7183$ family. d, Generation of Pa2-5/8. V_H-D-N-J_H3 sequences are presented as described above. The partial duplication of the seven terminal VH nucleotides is underlined. The reading frame of the $V_{\rm H}$ and $J_{\rm H}$ coding sequence at the $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joint is indicated above the sequence. The $V_{\rm H}$ sequence of Pa2-5/8 is compared with that of PJ14 (ref. 4), a germline V_H segment of the VhQ52 family.

Rearrangement of a $V_H DJ_H$ complex was also seen in Pa2-5, another isolate of the 300-19 culture. Pa2-5 carried an aberrant $V_{\rm H}$ to $DJ_{\rm H}$ rearrangement on the A allele and a parental (300-19) DJ_{H} 3 complex on the B allele. The DJ_{H} 3-B allele is expressed in Pa2-5 as well as in 300-19 (ref. 8) and gives rise to a short $D\mu$ -chain of relative molecular mass, 55,000 (55K; Fig. 2b, lane 1). After 2 weeks of culture, we subcloned Pa2-5 and randomly chose 12 subclones to analyse their $J_{\rm H}$ rearrangements and μ production. One of these subclones, Pa2-5/8, expresses both μ and $D\mu$ -chains (Fig. 2b, lane 2). The presence of the $D\mu$ -chain suggested that the μ expression of Pa2-5/8 did not result from a regular V_H to DJ_H3 rearrangement on the B allele but rather from an alteration of the $V_{\rm H}DJ_{\rm H}^-$ A allele. A Southern blot analysis confirmed this interpretation (Fig. 2a). The 2.8-kb BamHI/EcoRI fragment of the DJH B allele was present in both lines while the 6.5-kb fragment of the Pa2-5 A allele was rearranged to a $J_{\rm H}$ -positive fragment of 5.5 kb in Pa2-5/8 (Fig. 2a, lanes 1, 2). Reprobing the Southern blot with V_{H^-} specific probes demonstrated that the $V_H DJ_H$ complexes of both Pa2-5 and Pa2-5/8 contained a $V_{\rm H}Q$ 52 element (data not shown). Because we have characterized and mapped most V_HQ52 elements used by 300-19 cells⁹, we could identify the rearranged $V_{\rm H}$ elements of Pa2-5 and Pa2-5/8 as being the two most 3' situated V_H segments of the VhQ52 family (for definition of $V_{\rm H}$ families see refs 13-15). This suggested that the $V_{\rm H}Q52$ sequence in the $V_{\rm H}DJ_{\rm H}^-$ complex of Pa2-5 was replaced in Pa2-5/8 by a neighbouring $V_{\rm H}$ segment.

To further characterize the unexpected rearrangement in the P17 and Pa2-5 culture, we cloned the $V_{\rm H}DJ_{\rm H}^-$ alleles of P17 and Pa2-5 as well as the newly generated productive rearrangement of P17-32 and Pa2-5/8. The sequence of the P17 $J_{\rm H}$ alleles (Fig. 3a) confirmed that both had assembled a $V_{\rm H}DJ_{\rm H}$ complex by joining either a $V_{\rm H}7182$ (allele A) or a $V_{\rm H}441$ element (allele B) to the previously sequenced $DJ_{\rm H}3$ complexes of $300 \cdot 19^8$.

Methods. All $V_{\rm H}DJ_{\rm H}$ alleles were cloned as $J_{\rm H}$ -positive EcoRI fragments in either CH16A or CH35⁴². Restriction fragments carrying the respective rearrangement were subcloned into pUC-19 and sequenced according to Maxam and Gilbert⁴³. The Vh family of the rearranged $V_{\rm H}$ segments was determined by a comparison of their amino-acid sequence to a representative collection of $V_{\rm H}$ sequences¹⁵ and by a blotting analysis using $V_{\rm H}$ -specific pobes⁴¹.

Both $V_H DJ_H$ alleles of P17 carry the V_H and J_H coding sequences in different reading frames (see circled nucleotides in Fig. 3a), thus explaining the absence of μ production in P17. A similar out of phase joint has also occurred in the V_H to DJ_H rearrangement of Pa2-5 (Fig. 3d). The rearranged A allele of P17-32 carries a V_HDJ_H complex which obviously was derived from the $V_H DJ_H^-$ complex of P17-A because both complexes contain identical $D-N-J_H$ 3 sequences (Fig. 3b, c). The $V_HDJ_H^+$ complex of P17-32-A also contains a V_H7183 segment whose determined sequence (see legend to Fig. 3b), however, differs from that of P17-A by an exchange of four nucleotides and a deletion of four nucleotides at the V_{H} -D border (Fig. 3b).

How can the new $V_H DJ_H$ complex of P17-32-A have been generated from that of P17-A? Although alternative explanations exist¹⁶, we suggest that the P17-32-A V_HDJ_H complex results from a V_H to $V_H DJ_H$ joining event. The V_H sequence of P17-A as well as that of most $V_{\rm H}$ elements contains the conserved heptamer TACTGTG seven nucleotides away from the 3' end (boxed in Fig. 3). As also noted by others¹⁷, the sequence of this internal V_H heptamer is identical to that of 5' D heptamers (see Fig. 3c). Therefore, like a DJ_H complex, a V_HDJ_H complex carries a 5' heptamer and thus could be partner in the joining to a new $V_{\rm H}$ segment. Figure 3c depicts the proposed steps in such a $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joining to generate P17-32-A. The joining would start with a precise cut in P17-A at the very end of the internal V_H heptamer, followed by the terminal deletion of seven V_H and two D'nucleotides and the addition of a new 5'-located $V_{\rm H}$ 7183 element to the remaining $D-N-J_{\rm H}$ 3 sequences. In Pa2-5/8 the $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joint obviously occurred without any nucleotide deletion or addition (Fig. 3d, see vertical line between the heptamers), resulting in a $V_{\rm H}DJ_{\rm H}^{-1}$ complex with a partial duplication of the last seven $V_{\rm H}$ nucleotides (underlined in Fig. 3d). Both the $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joints described brought the $V_{\rm H}$ and $J_{\rm H}$ coding sequence back into the same reading frame and thus allowed μ expression.

The consensus recognition sequence consists of a conserved heptamer and nonamer separated by a spacer of either 12 or 23 base pairs and joining normally occurs only between segments flanked by recognition sequences of different spacer length $(12/23 \text{ joining rule})^{1,4}$. The V_H to $V_H DJ_H$ joining seems to violate this rule because it employs an isolated heptamer in the $V_{\rm H}$ sequence of the $V_H DJ_H$ complex. Joining events involving an isolated heptamer, however, also occur at the mouse and human κ locus and seem to be a possible variation of the rearranging process $^{18-20}$. The $V_{\rm H}$ replacement of Pa2-5/8 seems to involve two neighbouring $V_{\rm H}$ segments and the same may be true for P17-32 where the $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joint did not result in the deletion of many V_H 7183 germline segments (data not shown). The use of neighbouring V_H segments in the V_H to $V_H DJ_H$ joint may be connected with the local activation of $V_{\rm H}$ germline transcripts on a V_HDJ_H allele, and stresses the known correlation between

transcription and rearrangement at the immunoglobulin loci²¹⁻²⁶. Wang and Calame²⁷ have described the transcription of a normally silent V_H germline segment in B cells which carry a $V_{\rm H}DJ_{\rm H}$ complex 16 kb downstream from this $V_{\rm H}$ segment. The upstream $V_{\rm H}$ transcription is thought to be activated once the $V_{\rm H}$ to $DJ_{\rm H}$ joint has placed the immunoglobulin H gene enhancer element close to the 5'-located $V_{\rm H}$ segment. The local action of the H gene enhancer ²⁸⁻³⁰ may also be an explanation for the local activation of the V_H to $V_H DJ_H$ joint. Thus our studies support the idea of a dual function of the H gene enhancer, namely to provide transcriptional as well as recombinational enhancement^{2,31}

By completely replacing one $V_{\rm H}$ sequence by another (see P17-32), a $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joint may generate a $V_{\rm H}DJ_{\rm H}$ sequence indistinguishable from that derived from a V_H to DJ_H joint. Thus the importance and frequency of V_H to V_HDJ_H joints during B-cell development cannot easily be evaluated from an analysis of published $V_H DJ_H$ sequences³². In the two subclones analysed, however, $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joining seems to occur with a frequency similar to that of V_H to DJ_H rearrangements in the 300-19 culture⁹. Furthermore, the internal $V_{\rm H}$ heptamer which mediates the $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joint is highly conserved in most mouse and human $V_{\rm H}$ segments³². Specifically, the heptamer is found in V_H segments of all mouse Vh families except those of Vh J606, the most 5' located Vh family 14 . Most of the V segments of other gene loci $^{33-35}$ (those of the immunoglobulin light chains or T-cell receptor chains) do not carry an internal V heptamer with the interesting exception of the T-cell receptor γ-chain where the heptamer has been found in all mouse and human

 V_{γ} segments sequenced³⁶⁻³⁸.

The strong conservation of the internal $V_{\rm H}$ heptamer suggests that V_H to $V_H DJ_H$ joining is important for the generation of functional $V_H DJ_H$ complexes at the V_H locus. Indeed, a V_H to $DJ_{\rm H}$ joint can occur only once on a $J_{\rm H}$ allele because all germline D segments which are mediating the V_H to J_H joint are deleted during the joining process³. Statistically, two out of three $V_{\rm H}$ to $DJ_{\rm H}$ joints place the $V_{\rm H}$ and $J_{\rm H}$ coding sequences in different reading frames, generating up to 50% of null pre-B cells with aberrant $V_{\rm H}DJ_{\rm H}$ complexes on both $J_{\rm H}$ alleles. The $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joining mechanism may have specifically evolved to rescue these null pre-B cells. $V_{\rm H}$ replacements could occur repeatedly on a $J_{\rm H}$ allele, increasing its chance of generating a productive $V_{\rm H}DJ_{\rm H}$ complex which leads to the expression of a μ -chain. V segments of other V-gene loci (see above) may not need a V replacement mechanism because they have the possibility of multiple V to J joints^{39,40}. The consequences of the $V_{\rm H}$ to $V_{\rm H}DJ_{\rm H}$ joining mechanism for allelic exclusion, VH usage and generation of diversity in developing B cells are being investigated.

We thank Lise Leclercq and Klaus Rajewsky for critical reading of this manuscript. This work was supported by BMFT grant BCI-0365/2, Project 12.

Recombination between an expressed immunoglobulin heavy-chain gene and a germline variable gene segment in a Ly 1⁺ B-cell lymphoma

Robert Kleinfield*, Richard R. Hardy†, David Tarlinton†, Jeffery Dangl†, Leonard A. Herzenberg† & Martin Weigert*

* Institute for Cancer Research, Philadelphia, Pennsylvania 19111, USA † Department of Genetics, Stanford University, Stanford, California 94305, USA

The early stages of murine B-cell differentiation are characterized by a series of immunoglobulin gene rearrangements which are required for the assembly of heavy(H)- and light(L)-chain variable regions from germline gene segments. Rearrangement at the heavychain locus is initiated first and consists of the joining of a diversity $(D_{
m H})$ gene segment to a joining $(J_{
m H})$ gene segment. This forms a $DJ_{\rm H}$ intermediate to which a variable $(V_{\rm H})$ gene segment is subsequently added. Light-chain gene rearrangement follows and consists of the joining of a V_L gene segment to a J_L gene segment: once a productive light-chain gene has been formed the cell initiates synthesis of surface immunoglobulin M (sIgM) receptors (reviewed in ref. 1). These receptors are clonally distributed and may undergo further diversification either by somatic mutation^{2,3} or possibly by continued recombinational events⁴. Such recombinational events have been detected in the Ly 1+ B-cell lymphoma NFS-5, which has been shown to rearrange both λ and H-chain genes subsequent to the formation of sIgM $(\mu\kappa)$ molecules⁵. Here we have analysed a rearrangement of the productive allele of NFS-5 and found that it is due to a novel recombination event between V_H genes which results in the replacement of most or all of the coding sequence of the initial $V_{\rm H}Q52$ rearrangement by a germline $V_{\rm H}7183$ gene. Embedded in the $V_{\rm H}$ coding sequence close to the site of the cross-over is the sequence 5' TACTGTG 3', which is identical to the signal heptamer found 5' of many $D_{\rm H}$ gene segments⁶. This embedded heptamer is conserved in over 70% of known $V_{\rm H}$ genes⁷⁻¹⁷. We suggest that this heptamer mediates $V_{
m H}$ gene replacement and may play an important part in the development of the antibody repertoire.

The Ly 1⁺ B-cell lymphoma NFS-5 was generated by inoculating a newborn NFS/N mouse with ecotropic murine leukaemia virus (Cas 2SM)¹⁸. Recent studies have indicated that this lymphoma is capable of expressing a number of distinct surface immunoglobulin phenotypes during growth in vitro⁵. Analysis of primary cultures of NFS-5 on the fluorescence-activated cell sorter (FACS) shows a $\mu^-\kappa^-$ population from which $\mu^+\kappa^-$ cells spontaneously arise. Kappa light-chain synthesis can be induced by treatment with the B-cell mitogen lipopolysaccharide (LPS), to give a $\mu^+ \kappa^+$ population. Continued growth of these κ expressing cells in LPS results in the appearance of a small population, comprising 1-5% of the culture, expressing λ light chains. These λ -expressing cells generally have a $\mu^+\lambda^+$ surface phenotype, however $\mu^+\kappa^+\lambda^+$ co-expressors have also been detected. Hardy et al. have cloned a series of cell lines representing each of the various phenotypic forms of NFS-5 (ref. 5). These cloned lines have been designated as follows: 5.3 ($\mu^+ \kappa^-$), 5.4κ $(\mu^+\kappa^+)$, $5.4\kappa\lambda$ $(\mu^+\kappa^+\lambda^+)$ and 5.4λ $(\mu^+\lambda^+)$. The two λ expressing lines, 5.4κλ and 5.4λ, which represent progeny derived from a single expanded population of 5.4k, contain immunoglobulin gene rearrangements not present in either the parental lymphoma or the $\mu^+\kappa^+$ precursor, 5.4 κ . Thus, although all lines contain shared rearrangements on both κ alleles, lines differ in the organization of both the λ and H-chain genes. Distinct rearrangements at the λ locus are found in 5.4 $\kappa\lambda$ and

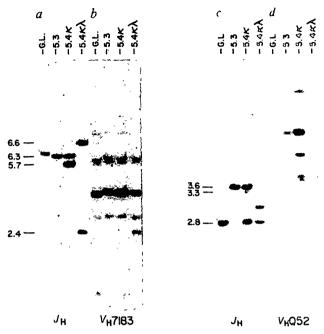

Fig. 1 Context of immunoglobulin variable (V_H) and joining (J_H) gene segments in NFS-5-derived cell lines. Approximately 10 µg of genomic DNA was digested with either EcoRI (a, b) or Hindl! (c, d), fractionated on 0.8% agarose gels and transferred to nitrocellulose filters²⁷; duplicate blots were assayed for hybridization to the ³²P-labelled $J_{\rm H}$ probe, pJ11 $(a,c)^{28}$, and to either a $V_{\rm H}7183$ (b) or $V_{\rm H}Q52$ (d)²⁹ gene probe. After hybridization, blots were first washed at low stringency (3×SSC, 68 °C) and then at high stringency (0.2×SSC, 68 °C). The cell lines assayed include: 5.3 $(\mu^+\kappa^-)$, 5.4 κ $(\mu^+\kappa^+)$ and 5.4 $\kappa\lambda$ $(\mu^+\kappa^+\lambda^*)$. G.L., germline DNA from a NFS/N×NZB RI line homozygous for the NFS/N heavy-chain locus. The J_H region probe, pJ11, consists of a 2.0-kb BamHI/EcoRI fragment containing the J_H3 and J_H4 gene segments subcloned into pBR322; the V_HQ52 probe (pV_HQ52NHhal) consists of a 0.3-kb HhaI fragment subcloned into the Smal site of puC12; the V_H7183 probe (pV_HSAPC-15) derives from a 0.9-kb EcoRI/HaeIII restriction fragment subcloned into the EcoRI/SmaI site of puc12. The 4.1-kb fragment seen in all lanes of c and d is due to plasmid contamination. Sizes (in kb) of restriction fragments hybridizing to both VH and JH probes are given on the left of the autoradiographs. The 3.3-kb fragment in c represents a nonproductive $V_{\rm H}DJ_{\rm H}2$ rearrangement (see text, and data not shown). The light hybridization of this band is thought to be due to a HindIII site between the JH3 and JH4 gene segments which cuts the pJ11-hybridizable region into two fragments of 2.8 and 3.3 kb; the 3.3-kb fragment contains the variable region and 400 bases of sequence hyridizable to pJ11.

5.4 λ ; whereas 5.4 $\kappa\lambda$ contains a $V_{\lambda}1J_{\lambda}1$ gene, 5.4 λ has a rearranged $V_{\lambda}2J_{\lambda}2$ gene⁵. As these rearrangements are not evident in either the parental lymphoma or 5.4 κ , λ light-chain gene recombination has occurred during growth in vitro. In addition, these λ -expressing lines are unusual in that they contain H-chain gene rearrangements not present in the $\mu^{+}\kappa^{-}$ precursor, 5.4 κ . As both H-chain alleles in 5.4 κ consist of complete $V_{\rm H}DJ_{\rm H}$ variable regions, these 'secondary' H-chain gene rearrangements have been investigated further.

DNA of high relative molecular mass (M_r) from NFS-5.3, 5.4 κ and 5.4 κ λ was digested with either EcoRI or HindIII and analysed by Southern blot hybridization using the J_H -region probe, pJ11 (Fig. 1a, c). Both H-chain alleles of 5.4 κ are rearranged and detected in HindIII digests as 3.6-kilobase (kb) and 3.3-kb restriction fragments (Fig. 1c). Restriction fragments of identical size are detected using a V_HQ52 gene probe (Fig. 1d), suggesting that these rearrangements consist of complete V_HDJ_H joins which utilize V_H genes belonging to the V_HQ52 gene family. This conclusion is supported by Northern

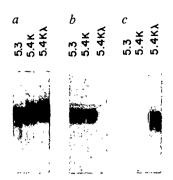

Fig. 2 Northern blot analysis of total RNA from NFS-5-derived cell lines using C_{μ} (a), $V_{\rm H}$ Q52 (b) and $V_{\rm H}$ 7183 (c) gene probes. Total cellular RNA was prepared from homogenized cells lysed in 6 M urea/3 M LiCl, extracted with phenol/chloroform and ethanol-precipitated³⁰. Approximately 10 μ g of RNA from each cell line was electrophoresed through a 1.5% agarose/formal-dehyde gel³¹, transferred to nitrocellulose and hybridized with nick-translated ³²P-labelled probe in 50% formamide, 5×SSC, 1×Denhardt's, 20 mM NaHPO₄ pH6.5, 10% dextran sulphate at 42 °C (ref. 32). Blots were initially washed at low stringency (2×SSC, 0.1% SDS, 52 °C), followed by high-stringency washes (0.1×SSC, 0.1% SDS, 52 °C). Transcript sizes correspond to those expected for mature μ mRNA.

blot analysis which indicates that 5.4κ synthesizes a mature transcript that hybridizes to both C_{μ} (Fig. 2a) and $V_{\rm H}Q52$ (Fig. 2b) gene probes. This transcript appears to be encoded by the 3.6-kb HindIII restriction fragment, as the $\mu^+\kappa^-$ cell line, 5.3, which has retained this restriction fragment but deleted the 3.3-kb fragment (Fig. 1c), nevertheless continues to produce both mature μ messenger RNA (Fig. 2a) and protein¹⁸. We conclude that the 3.6-kb HindIII fragment contains the productive H-chain allele. This allele is rearranged to $J_{\rm H}4$ because the 5.3 cell line, which is haploid at the J_H locus (see Fig. 1a, c), has deleted the 2.8-kb germline-encoded HindIII fragment; this deletion is diagnostic of rearrangements to $J_{\rm H}4$ (Fig. 1c). The 3.3-kb HindIII fragment contains a J_H2-rearranged H-chain allele, as determined both by hybridization using J_{H} -specific probes and detailed restriction mapping of the cloned allele (R.K., unpublished data). This allele appears to be nonproductive as $J_{\rm H}2$ -containing transcripts cannot be detected in 5.4 κ RNA (data not shown).

Continued rearrangement of both the productive and nonproductive H-chain alleles is evident in $5.4\kappa\lambda$. The relationship between these alleles has been determined by Southern blot analysis using $J_{\rm H}1-J_{\rm H}2$ and $J_{\rm H}3-J_{\rm H}4$ -specific probes (data not shown). Rearrangement of the nonproductive allele results in a

change in the HindIII fragment size, from 3.3 to 2.8 kb (Fig. 1c). The 2.8-kb $J_{\rm H}$ -hybridizable fragment is also detected using the $V_{\rm H}O52$ probe (Fig. 1d), indicating that this allele still contains a complete V_HQ52DJ_H rearrangement. Accompanying this rearrangement, germline genes in both the $V_{\rm H}Q52$ (Fig. 1d) and $V_{\rm H}$ 7183 (Fig. 1b) gene families have been deleted suggesting an event occurring over many kilobases of DNA extending from the $J_{\rm H}$ region to the germline $V_{\rm H}$ locus. Rearrangement of the productive allele in 5.4kh is accompanied by a change in the HindIII fragment from 3.6 to 3.0 kb (Fig. 1c), and a change in the EcoRI fragment from 6.3 to 2.4 kb (Fig. 1a). As shown in Fig. 1d, the 3.0-kb fragment does not hybridize to the $V_{\rm H}Q52$ gene probe, despite its derivation from the 3.6-kb $V_{\rm H}Q52$ containing variable region (see above). Rather, as shown in the EcoRI digests, the productive allele of 5.4κλ, contained on a 2.4-kb fragment (Fig. 1a), hybridizes to a $V_{\rm H}7183$ gene probe. Thus, secondary rearrangement of the productive allele results in replacement of the initial $V_{\rm H}Q52$ gene by a $V_{\rm H}7183$ gene. Northern blot analysis of total RNA from 5.4kh indicates that this replacement is accompanied by a change in V_H RNA expression from $V_{\rm H}Q52$ to $V_{\rm H}7183$ (Fig. 2c).

To gain insight into the mechanism of this $V_{\rm H}$ gene replacement, we have sequenced the expressed variable regions of 5.4κ and 5.4κλ using RNA primer extension techniques¹⁹. Analysis of 5.4 κ yields a single $V_{\rm H}Q52DJ_{\rm H}4$ sequence (Fig. 3), indicating that the remaining V_HQ52 rearrangement (the 5.7-kb EcoRIfragment in Fig. 1) in this cell line does not accumulate RNA to any significant extent and is therefore nonproductive at the phenotypic level. Analysis of the H-chain mRNA in 5.4κλ similarly yields a single $V_{\rm H}7183DJ_{\rm H}4$ sequence. No $V_{\rm H}Q52$ transcript is detected in these cells by Northern analysis (Fig. 2b), indicating that the remaining $V_{\rm H}Q52$ rearrangement (the 6.6-kb EcoRI fragment) is not expressed. As the productive $V_{\rm H}$ 7183 rearrangement in 5.4 $\kappa\lambda$ derives from a $V_{\rm H}$ Q52 rearrangement, V_H gene replacement has occurred during propagation in vitro. This conclusion is supported by sequence identity of the N, $D_{\rm H}$ and $J_{\rm H}$ segments expressed in 5.4 κ and 5.4 $\kappa\lambda$. The N sequences are of particular interest as they are created de novo during the V-D recombinational process. Identity of N sequences confirms the common origin of these alleles (see Fig. 3). The variable gene segments of these alleles, however, show marked differences in sequence. Comparison of the 5.4k sequence with a representative germline $V_{\rm H}Q52$ sequence (M141; ref. 16) confirms that this gene is a member of the $V_{\rm H}Q52$ gene family. A similar comparison of the 5.4κλ sequence with a representative germline $V_{\rm H}7183$ sequence ($V_{\rm H}E4.30$; ref. 15) establishes that the productive allele of 5.4kh is derived from a member of the $V_{\rm H}7183$ gene family. Recombination, therefore, results in replacement of most or all of the coding sequence of

Fig. 3 Nucleotide sequence comparison between the expressed alleles of 5.4κ and $5.4\kappa\lambda$. Sequence homologies are shown and reference $V_{\rm H}Q52$ (MOPC 141)¹⁶ and $V_{\rm H}7183$ ($V_{\rm H}E4.15$)¹⁵ germline sequences are given to indicate $V_{\rm H}$ gene family relationships (>80% sequence homology)³⁰. Because of identity in the terminal three bases of the $V_{\rm H}$ segments, the exact site of the recombination cannot be determined precisely; however, four bases 5' of the $V_{\rm H}D_{\rm H}$ junction, a single germline-encoded base difference between 5.4κ (cytosine) and $5.4\kappa\lambda$ (adenine) indicates the 5' boundary of the recombination. Base sequences identical to the recombination signals found 5' of many D elements (5'TACTGTG 3')¹⁷ are boxed.

Methods. Sequences were obtained using RNA primer extension techniques according to Shlomchik et al.¹⁹. Briefly, total cellular RNA was extracted in guanidinium isothiocyanate³³, and poly(A)⁺ RNA was selected on oligo-(dT)-cellulose columns³². Synthesis of complementary DNA was primed with 50 ng of the 5'-end-labelled oligonucleotide (5'GCAGGAGAGGAGGGGGGA 3') homologous to μ constant-region exon 1. Labelled primer was annealed to 80-120 μ g of poly(A)⁺ RNA, and reverse transcription carried out in 100 mM Tris(8.3), 140 mM KCl, 10 mM MgCl₂, 0.5 mM dNTP₅, 10 mM dithiothreitol, 120 U RNasin, 40 U reverse transcriptase for 2 h at 42 °C. The cDNA was obtained by fractionation on a 5% polyacrylamide/7M urea gel for 2-3 h at 30 V cm⁻¹. Gel slices were chopped and eluted overnight at 37 °C in 0.5 M NH₄Ac, 1 mM EDTA. Full-length cDNA was ethanol-precipitated and washed extensively before sequencing by modified chemical degradations, as described by Rubin and Schmid³⁴ and Bencini et al.³⁵.

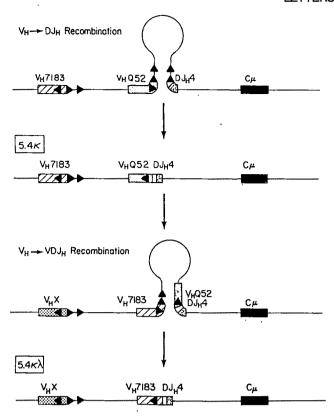

Fig. 4 Model of the $V_{\rm H}$ gene recombinations leading to the formation of the expressed H-chain allele of 5.4κλ. Heptameric and nanomeric signal sequences are indicated by black arrows, and component gene segments are indicated by patterned overlays. Both N and D_{SP2} sequences are depicted together in the figure as an open box. Top panel shows the initial V_HQ52 to DJ_H4 recombination, involving interaction of signal sequences found 3' of the $V_{\rm H}Q52$ gene with those 5' of the $DJ_{\rm H}4$ complex to form a hypothetical stem-loop structure. Excision at the base of the stem and fusion of $V_{\rm H}Q52$ gene to $DJ_{\rm H}4$ completes the formation of the intact variable region of 5.4k. Subsequent recombination between an upstream germline $V_{\rm H}7183$ gene segment and the productive $V_{\rm H}$ Q52 rearrangement is postulated to occur via interaction of the heptameric and nonameric signal sequences 3' of the V_H7183 gene with the embedded heptamer of the rearranged $V_{\rm H}$ Q52 gene, resulting in the replacement of the $V_{\rm H}$ Q52 coding region by a $V_{\rm H}$ 7183 gene segment. This recombination is precise, and does not result in the addition or deletion of bases: the 5' portion of the newly formed variable region is contributed by the incoming V_H 7183 gene, whereas the 3' portion, consisting of N, $D_{\rm SP2}$ and $J_{\rm H}4$ sequences, has been retained from the recombinations which initially formed the allele.

the resident $V_{\rm H}$ Q52 gene with that of the incoming $V_{\rm H}$ 7183 gene. This recombination has occurred so as to maintain a continuous open reading frame. Because of the identity of the 3'-terminal three bases of the germline $V_{\rm H}$ gene segments (both gene families use an AGA for this codon), the precise 3' point of the recombination cannot be identified. However, a single germline-encoded base difference between 5.4κ and $5.4\kappa\lambda$ delineates the 5' boundary of the recombination four bases 5' to the V-D junction.

A number of mechanisms such as gene conversion⁴ and homologous recombination²⁰ may be invoked to explain this $V_{\rm H}$ gene replacement. We consider yet a third model of $V_{\rm H^-}V_{\rm H}$ recombination by a mechanism analogous to V_{H} - D_{H} recombination. Embedded in the V_H coding region, close to the site of the recombination, is the sequence 5' TACTGTG 3'21, which is identical to the signal heptamer found 5' of many $D_{\rm H}$ gene segments¹⁷. We suggest that this heptamer functions as a pairing element in mediating V_{H} - V_{H} recombination (see Fig. 4). Here

a $V_{\rm H}$ O52 gene is paired by its 3' signal sequences to the signal sequences found 5' of DJ_H4 ; shown as a stem-loop structure. Endonucleolytic cleavage at the base of the stem, and fusion of the $V_{\rm H}Q52$ gene segment to this $DJ_{\rm H}4$ intermediate results in the formation of the productive allele found in 5.4k. Further rearrangement of this allele is postulated to occur by an interaction between the embedded heptamer of the $V_{\rm H}Q52$ gene and the signal sequences 3' of one of the germline $V_{\rm H}7183$ genes still present on the chromosome. This results in the replacement of the $V_{\rm H}Q52$ gene by a $V_{\rm H}7183$ gene to give the productive allele found in $5.4\kappa\lambda$.

Although conventional immunoglobulin gene recombination is correlated with the presence of both heptameric and nonameric signal sequences, recombination at isolated heptamers has also been reported. A precedent for heptamer-mediated recombination has been obtained at the k locus, where rearrangements of both V_{κ} and J_{κ} gene segments to an isolated heptamer in the J_{κ} - C_{κ} intron have been reported^{20,22}. Moreover, in many λ-producing plasmacytomas and hybridomas, deletion of the C_{κ} gene segment is mediated by a recombinational event between this intron heptamer and heptamer-nonamer sequences located 3' of the C_{κ} locus (such C_{κ} deletion has not, however, been observed in $5.4\kappa\lambda$)^{23,24}. It has been suggested that such a deletion may be an important preamble to λ gene recombination²³, implying that these heptamer-mediated recombinations may have biologically important consequences.

Yancopoulos et al.15 and Perlmutter et al.25 have recently described the preferential usage of $V_{\rm H}$ genes from the J-most proximal V_H gene family early in fetal development. This preference is not evident in the adult repertoire where the $V_{\rm H}$ gene families appear to be used at frequencies reflecting the relative complexity of each gene family²⁶. We suggest that V_H gene replacement mediated by the embedded heptamer may represent one mechanism leading to the random V_H usage observed in the adult repertoire. Indeed, the strong conservation of this heptameric sequence within the FR3 region where it encodes Tyr and Cys residues at positions 91 and 92 supports this hypothesis: over 70% of $V_{\rm H}$ genes which have been examined, including all functional members of the J-proximal $V_{\rm H}$ families (for example, $V_{\rm H}7183$, $V_{\rm H}Q52$ and $V_{\rm H}S107)^{7-17}$, have been found to contain this heptameric sequence. Thus, conservation is evident not only at the amino-acid sequence level, but also at the nucleotide level where little, if any, third base degeneracy is observed at both the Tyr and Cys codons. Such a high degree of conservation, even among highly diverged $V_{\rm H}$ gene families, suggests that this heptameric sequence has an important role in the somatic diversification of the antibody repertoire.

Distinct factors bind to apparently homolgous sequences in the immunoglobulin heavy-chain enhancer

Judah Weinberger*†§, David Baltimore†‡ & Phillip A. Sharp*†

* Center for Cancer Research and † Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA ‡ Whitehead Institute for Biomedical Research, Cambridge, Massachusetts 02142, USA

The intron separating the variable- and constant-region exons of the rearranged immunoglobulin heavy-chain locus contains a lymphocyte-specific transcriptional enhancer^{1,2}. The enhancer is a member of a class of cis-acting, tissue-specific, transcriptional control elements which are characterized by orientation-independent and relatively position-independent function^{1,2}. In vivo analysis of the position of DNA-binding factors, by assessing the availability of specific bases to chemical modification, has identified four sequence clusters within the heavy-chain enhancer, denoted E1 to E4 (refs 3, 4). These sites are protected (that is, occupied) only in B lymphocytes. A consensus sequence relationship (consensus CAGGTGGC) between these four sites was suggested where three of the sites conformed to the consensus in seven of eight positions while the other was homologus in six of eight positions. We proposed that a single trans-acting factor might recognize all four sites^{3,4}. Using an assay involving gel electrophoresis of DNA-protein complexes⁵⁻⁸ to detect sequence-specific DNA binding factors that recognize these related motifs, we have now identified a mouse B-cell nuclear factor (NF-µE1) which binds specifically to one such motif within the mouse heavy-chain gene enhancer. This factor binds poorly, if at all, to the other related motifs, and other factors have been identified which interact preferentially with some of these latter motifs. Dimethyl sulphate interference experiments suggest that the NF-µE1 factor is in contact with at least the guanine residues in the sequence GATGGCCGATC. This factor seems to be present in both lymphoid and non-lymphoid cell lines.

First, we searched for enhancer-binding factors for these sequence clusters in nuclear extracts from B-cell lines. For this we used a gel electrophoresis DNA-binding assay⁵⁻⁸ in which DNA-protein complexes are resolved by their slower mobility in a low-ionic-strength polyacrylamide gel. A 221-base pair (bp) HinfI fragment containing all in vivo identified binding sites was subcloned into the SmaI site of the pUC-13 vector (Fig. 1). The HindIII-PoulI fragment containing the E1 site and a segment of the polylinker (henceforth denoted as the E1 probe)

§ Permanent address: Department of Medicine, Harvard Medical School, Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts 02115, USA

was 3'-end-labelled and then incubated with increasing amounts of nuclear extract derived from a mouse B-cell lymphoma line. WEHI-231. The duplex alternating copolymer poly(dIdC) poly(dI-dC) was included in the binding reaction to suppress the effect of sequence-nonspecific binding of proteins. A distinct band, a putative protein-DNA complex, with a slower electrophoretic mobility than the free fragment, was observed (Fig. 2a). At higher concentrations of input nuclear extract, additional distinct species with even further retarded mobilities were noted. Competition experiments showed that these species resulted from non-sequence-specific complex formation (data not shown). To test the sequence-specific nature of the major complex, we examined the ability of DNA fragments containing the E1 sequence or other sequences to compete for factor binding to the E1 probe. Two restriction fragments were derived from the mouse immunoglobulin heavy-chain enhancer region. The 400-bp XbaI-PstI fragment (µ400), which contains E1 sequences (Fig. 1), efficiently competed with radiolabelled E1 probe for binding (Fig. 2b). A 300-bp PstI-EcoRI fragment (μ300) containing the balance of the enhancer (Fig. 1), including a partial E2 site and complete E3 and E4 sequences, was, however, unable to compete for NF-µE1 binding of the test fragment. Molar ratios of competitor DNA to probe DNA of 20-50 did not reduce the level of specific binding. Thus, there is no high-affinity NF-µE1-binding site in the µ300 fragment.

The µ300 fragment is recognized by two distinct factors which generate distinct mobility complexes in the gel shift assay8,9. One of these, IgNF-A, recognizes an octamer motif, ATTTGCAT, conserved between the mouse immunoglobulin heavy- and light-chain promoters, as well as the heavy-chain enhancer⁸. Another sequence-specific factor binds to a 70-bp AluI fragment containing E39. A possible way in which the four binding sites occupied in vivo might result from binding of a single factor, and yet without DNA containing the E3 site competing for binding to the E1 site, would be if binding to the E3 site was of lower affinity. To assess this possibility, a 5'-endlabelled E3 probe, the 70-bp AluI frgment, was incubated in WEHI-231 nuclear extract together with either μ400, containing the E1 site, or µ300, containing the balance of the known in vivo binding sites. Figure 2b shows that binding to the E3 probe was not efficiently competed for by excess E1 binding sites while the same binding was efficiently competed for by homologous sequences in the µ300 fragment. Titrations of low molar ratios of µ400 and µ300 fragments compete for E1 and E3 probe

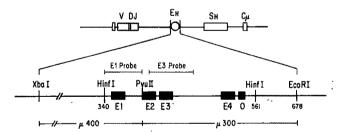

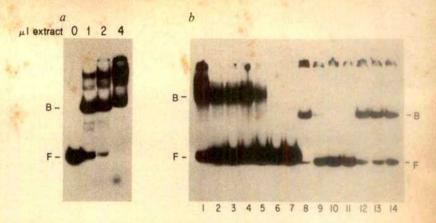

Fig. 1 Scheme of probes and competitor fragments used. The immunoglobulin heavy-chain locus is shown with the intron containing the enhancer (open circle) and the μ switch region (S_H, open bar) separating the rearranged V-D-J (variable-diversityjoining) exons and C_{μ} , the constant-region μ -chain gene. The enhancer is located in a 678-bp XbaI-EcoRI fragment with the indicated restriction sites. E1-E4 and O refer to sequences that are protected from chemical modification in intact B cells³ or in their nuclei4. The HinfI fragment, containing all the indicated sites, was blunted and subcloned into the Sma I site of pUC-13. The E1 probe was derived by cutting the resulting plasmid with HindIII, in the polylinker, and PvuII. The E3 probe is the 70-bp AluI fragment spanning the indicated region. A PstI site used for deriving two fragments indicated on the lowest line, µ400 and µ300, is located 6 bp downstream of the PvuII recognition site.

Fig. 2 Binding of a nuclear factor to E1 and competition analysis. a, Binding in WEHI-231 nuclear extract. The E1 probe was incubated with nuclear extract as described below. The bound protein-DNA complex and free DNA fragment were resolved on a polyacrylamide gel. The free fragment is labelled F, and a bound complex, B, b, Competition analysis of binding to E1 and E3. Lanes 1-7, binding reactions using 1 ng of a $[5'-\alpha^{-32}P]$ -end-labelled 70-bp E3 probe. Lane 1, a control reaction in the absence of additional competitor DNA; Lanes 2-4, binding reactions carried out in the presence of 25, 75 or 150 ng, respectively, of the μ 400 fragment (Fig. 1). Lanes 5-7, binding reactions carried out in the presence of 25, 75 and 150 ng of the µ300 fragment. Lanes 8-14, binding reactions using 1 ng of a radiolabelled

65-bp E1 probe. Lane 8, a control reaction carried out in the absence of additional competitor DNA. Lanes 9-11, binding reactions carried out in the presence of 25, 75 and 150 ng, respectively, of the μ400 fragment. Lanes 12-14, binding reactions carried out in the presence of 25,

75 and 150 ng, respectively, of the µ300 fragment.

Methods. The E1 probe was excised as described for Fig. 1, end labelled with $[\alpha^{-32}P]$ dATP and the large fragment of Eschrichia coli DNA polymerase I, and isolated by polyacrylamide gel electrophoresis. The ^{32}P -labelled fragment (\sim 0.5 ng, 10,000 c.p.m.) was incubated with the nuclear extract 14 of a murine B-cell lymphoma, WEHI-231. Binding reactions (10 μ l) contained 10 mM Tris-HCl (pH 7.5), 50 mM NaCl, 1 mM dithiotreitol, 1 mM EDTA, 5% glycerol, 1,600 ng poly(dI-dC) poly(dI-dC), and the indicated amounts of nuclear extract. After incubation at room temperature for 10 min, the complexes were resolved on a 4% polyacrylamide gel (acrylamide: bisacrylamide weight ratio of 29:1) in 45 mM Tris-borate, 1 mM EDTA pH 8.0 buffer. The gel was dried and autoradiographed.

binding with the expected quantitation (data not shown). Thus, NF-µE1 and NF-µE3° represent distinct factors with high affinity for distinct cognate sequences. Similar competition experiments using the human immunoglobulin heavy-chain enhancer¹⁰ demonstrate the existence of NF-µE1- and NF-µE3°-binding sites in this fragment. No binding activity specific for E4 or E2 sequences has been detected; however, all the probes

used to date have been derived from fragments that were cut at the PstI site, which may interfere with binding.

To elucidate the critical contact points for the binding of NF-µE1 protein, DNA methylation interference analysis was performed11. Dimethylsulphate (DMS) methylates the N-7 position of guanine which extends into the major groove of the B-helix12. The E1 probe was partially methylated with DMS, a binding reaction was performed with the WEHI-231 nuclear extract, and bands of the free fragment and the protein-DNA complex were resolved as described in Fig. 2. Fragments recovered from these bands were cleaved at methylated guanine residues with piperidine and the cleavage products were displayed on denaturing sequencing gels. Positions at which methylation of guanine residues interferes with factor binding should not be cleaved in fragments recovered from the DNA-protein complex band. Comparison of the cleavage pattern of radioactive fragments from the two bands revealed several discrete sites on both strands of the E1 probe where methylation interfered with binding (Fig. 3). These data suggest that the binding site of the factor must include contacts with the guanine residues in the sequence GATGGCCG. The identified interfering guanine residues are precisely the residues protected against DMS methylation in vivo3. Delineation of contact residues for NF-µE1 binding underscores a lack of significant homology with other putative enhancer-binding sites. In particular, the sequences identified for E3 binding^{3,4}, TGTGGCAAG, differ from the E1-binding site by four of eight bases. Furthermore, the above methylation pattern of the E1 site suggests a recognition sequence that only partially overlaps the consensus homology previously deduced by comparison of the four in vivo binding

When nuclear extracts from a panel of pre-B cells, B cells, plasma cells, T cells and various non-lymphoid cells were assessed for the level of NF-µE1 activity (Fig. 4), all were found to contain an activity that generated a band with the E1 probe which co-migrated with the NF-µE1 band from WEHI-231 cells. Some cell lines showed evidence that minor species migrated more rapidly than the NF-µE1 band. These complexes may represent degradation products of NF-µE1 because repeated freezing and thawing of some nuclear extracts increased the levels. Competition experiments and methylation interference analysis performed in various non-lymphoid nuclear extracts revealed sequence specificity identical to that described above for B-cell nuclear extracts (data not shown).

The biological function of NF-µE1 and its biochemical mode

Fig. 3 Methylation interference analysis of binding to E1. The E1 probe was uniquely radiolabelled at the HindIII site in the polylinker (5' to Hinfl site of the enhancer, see Fig. 1) by the large fragment of E. coli DNA polymerase I (a) or by polynucleotide kinase (b). F and B refer, respectively, to DNA recovered from the free and bound species, the products of the binding reaction. A+G chemical cleavage ladders¹² of the E1 probe were co-electrophoresed to map the binding domain.

Methods. The probe (5 ng, 105 c.p.m.) was methylated with DMS for 8 min at 20 °C12 After ethanol precipitation, a 30-µl binding reaction was carried out using the methylated probe, 6 µl of WEHI-231 nuclear extract and 3,600 µg of poly(dI-dC) poly(dI-dC). The remain-3,600 µg of of the reaction conditions were as described in the Fig. 2a legend. The products of the reaction were resolved as in the Fig. 2a legend. After autoradiography to visualize the various species, DNA was eluted from the free

and bound fragments, and cleaved with 1 M piperidine in 100 µl at 90 °C for 30 min¹². After overnight lyophilization, the products were analysed by separation in an 8% polyacrylamide gel (19:1) in the presence of 8 M urea followed by autoradiography at -70 °C with an intensifying screen. Essentially the entire probe is displayed in this figure and the only interference sites detected are those indicated.

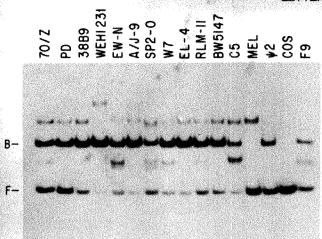

Fig. 4 Analysis of distribution of E1-binding activity in various cell types. Nuclear extracts were prepared 14 from murine or human pre-B-cell lines (70/Z, PD, 38B9), B-cell lines (WEHI-231, EW-N), a myeloma (W7), T-cell lines (EL-4, RLM-11, BW-5147), a primitive B-cell progenitor cell line¹ (C5, a derivative of Ba/F₃, a line like those described in ref. 15), an erythroid line (MEL), a fibroblast line (Ψ2), simian virus 40-transformed African green monkey kidney cell line (COS), and an embryonal cell line (F9). Binding reactions were carried out with the E1 probe as described in Fig. 2 legend. The results of the reaction were analysed by electrophoresis on native polyacrylamide gels. Autoradiography of the dried gels was performed at -70 °C with intensifying screens. Longer exposures of the autoradiogram reveal detectable levels of a species co-migrating with B, the bound complex, in MEL and COS cells.

of action are unknown. The evolutionary conservation of an E1-binding site between mouse and human immunoglobulin genes suggests an important biological function. Deletions of sequences containing the E1 site have been shown to produce severalfold reduction in the transcriptional stimulation activity of the immunoglobulin enhancer element in B cells^{2,13}. The E1 element may be a transcriptional control element, with either constitutive or lymphocyte-restricted transcriptional activation. Perhaps the most direct evidence for the involvement of binding to the E1 site is the previous in vivo methylation protection analysis. A factor is bound to the E1 site in situ which forms contacts with identical guanine residues to those found with the solubilized NF-µE1 factor³. This suggests that NF-µE1 is bound to the E1 site in B lymphocytes.

In the above studies, NF-µE1 binding in vivo was found only in cells of the B lineage. In vitro, however, factors with identical binding specificity are present in extracts from cells of nonlymphocytic lineage. Although similar binding specificities are defined, the proteins found in the various cell types may differ in important aspects that would not be detected by this assay. An obvious explanation for these apparently inconsistent observations is that the immunoglobulin enhancer is in an inactive conformation in non-B cells and thus inaccessible for binding by NF-µE1. The ubiquitous expression of an NF-µE1 activity suggests that this factor is probably important for expression of genes in non-lymphocytic cells. It is possible, for example, that NF-µE1 binding has completely different consequences in cells of different developmental lineages or stages or in different genomic contexts, including cis-dominant transcriptional suppression. These possibilities are being investigated.

Several sites (µE2, µE3 and µE4) with limited sequence homology to the E1-binding site have been identified within the immunoglobulin heavy-chain enhancer. It has been suggested that these four sites bind a common factor. Evidence presented here, in fact, suggests that this is not the case. NF-µE1 clearly does not bind to the µE3 or µE4 sites; conversely, a different factor, NF-µE3, binds with high affinity to E3 but does not bind El to a significant degree9. Thus, the immunoglobulin heavychain enhancer element must be recognized by at least three and probably more different factors. How the combination of these factors sum to a cell-type-specific enhancer is a fascinating problem.

We thank Dr L. Staudt for nuclear extracts from various cell lines, Dr A. Hayday for a plasmid containing the human heavychain enhancer, Drs J. LeBowitz and H. Singh for helpful discussions and a critical reading of the manuscript and M. Siafaca for preparation of the manuscript. J.W. acknowledges support from NIH Clinical Investigator Award HL01633. Deregulated expression of c-myc by murine erythroleukaemia cells prevents differentiation

E. V. Prochownik & J. Kukowska

Department of Pediatrics and the Committee on Cellular and Molecular Biology, C. S. Mott Children's Hospital, University of Michigan School of Medicine, Ann Arbor, Michigan 48109, USA

Friend murine erythroleukaemia (F-MEL) cells are a permanent line of primitive erythroid precursors originally derived from the spleens of mice infected with the Friend strain of murine leukaemia virus1. F-MEL cells differentiate in vitro in response to various chemical inducers^{1,2}. Concomitantly with induction, a biphasic regulation of c-myc oncogene transcripts is observed3. Within one hour of the addition of dimethyl sulphoxide (DMSO) or hypoxanthine (Hyp), the levels of c-myc transcripts fall dramatically and remain virtually undetectable for the next few hours. Between 8 and 24 hours after induction, c-myc transcripts return to preinduction levels and then decline again between 3 and 5 days as most of the cells undergo terminal differentiation. To explore the potential relationship between c-myc expression and F-MEL terminal differentiation, we have investigated here whether reversing the early fluctuations in c-myc transcript levels affects the ability of F-MEL cells to differentiate. We therefore constructed an amplifiable plasmid vector containing a full-length mouse c-myc complementary DNA and introduced it stably into recipient F-MEL cells. The exogenous c-myc sequences are transcribed in F-MEL cells and the transcript levels do not change significantly in response to inducing agents. The net result is continued c-myc expression following DMSO or Hyp induction and a complete or partial inhibition of F-MEL differentiation.

Figure 1 shows the plasmid used for transfections. The backbone of this vector has been derived from pSV₂neo, in which bacterial neomycin resistance (neo) sequences have been replaced with a full-length murine c-myc cDNA clone. The simian virus 40 (SV40) early splice and poly(A) sites of pSV₂neo have been retained. Downstream of myc and in the opposite transcriptional orientation, we have introduced an expressible

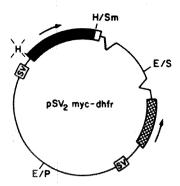

Fig. 1 Structure of an amplifiable mouse c-myc expression vector. SV, SV40 promoters; dark box, mouse myc cDNA sequences; light box, neo 3'untranslated region sequence; cross-hatched boxes, dhfr sequences SV40 splice junctions; H, HindIII; Sm, SmaI; E, EcoRI; S, SaII; P, PstI. Methods. All plasmids were purified by the alkaline lysis method plasmid pSV₂neo (ref. 28) was digested with HindIII and Smal to remove neo sequences and then treated with the large fragment of DNA polymerase I. A 1.5-kilobase (kb) HindIII fragment containing the entire coding region of a mouse c-myc cDNA was excised from the plasmid pMc-myc 54 (ref. 29), treated with the large fragment of DNA polymerase and ligated into the pSV₂neo-derived vector. The resultant plasmid, with c-myc sequences under the control of the SV40 early promoter, was treated with EcoRI and the large fragment of DNA polymerase. Into this site we cloned a 2.8-kb Pst1-Sal1 fragment from the plasmid pFR400 (ref. 4) after treating the fragment with T4 DNA polymerase and the large fragment of DNA polymerase to render it blunt-ended. This fragment contains the SV40 early promoter, a mutant dhfr cDNA and splice-polyadenylation sites derived from the gene encoding hepatitis-B virus surface antigen.

full-length cDNA encoding a mutant form of dihydrofolate reductase (dhfr) which facilitates a selective amplification of plasmid sequences in the presence of high concentrations of the antimetabolite methotrexate (MTX)⁴. We linearized pSV₂mycdhfr along with a selectable plasmid marker encoding neomycin resistance. The two plasmids were introduced by electroporation at a 10:1 molar ratio into recipient F-MEL-745 cells. We selected six clones which demonstrated resistance to both neomycin and MTX. Of these, three expressed the exogenously introduced c-myc sequences (not shown).

We first examined the levels of endogenous and exogenous c-myc transcripts in response to DMSO using an S₁ nuclease protection assay (Fig. 2). Transfected F-MEL cells were first removed from MTX-containing medium for 3-5 days, then washed and cultured in Dulbecco's minimal essential medium (DMEM) containing 1.5% DMSO for varying periods of time. Total RNAs were extracted and used in the S₁ protection assay. The results confirmed the previously reported changes in endogenous c-myc transcripts which occur after DMSO addition³. The behaviour of exogenous, pSV₂myc-dhfr-derived c-myc transcripts was quite different. Following the addition of DMSO. c-myc transcript levels declined by no more than 50%, remaining easily detectable even when endogenous transcripts were not. The net effect was therefore a partial reversal of the early DMSO-induced decline in c-myc transcript levels. Of particular interest was the failure of endogenous transcripts in transfected cells to decline significantly by day 5, suggesting that the cells still retained proliferative potential.

The experiments described above indicated that it was possible to reverse at least partially the inhibitory effects of DMSO on c-myc transcript levels. We therefore next investigated whether this reversal had any inhibitory effect on the differentiation capacity of F-MEL cells in response to two structurally unrelated inducers of differentiation. F-MEL cells were cultured for varying times in 1.5% DMSO or 5 mM Hyp. The extent of differentiation was monitored daily by determining the fraction of cells that stained with benzidine⁵. The results (Fig. 3) showed that in each of the three clones tested, the extent of benzidine positivity was significantly reduced in relation to non-transfected F-MEL-745 cells or to clones of F-MEL cells which had been

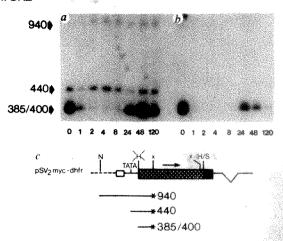

Fig. 2 Levels of mouse c-myc transcripts in F-MEL clone 13 (a) or 745 (b) following the addition of DMSO. The dark arrows indicate the 940-nucleotide reannealed input probe, the 440-nucleotide S₁-protected fragment representing pSV₂myc-dhfr-derived exogenous transcripts and the two unresolved 400- and 385-nucleotide fragments representing endogenous myc transcripts³⁰. Numbers below each lane indicate the length of time (in hours) that cells were incubated in the presence of DMSO. c, The S₁ probe was a 940-nucleotide long Nde1-XhoI fragment, derived from pSV₂ myc-dhfr and end-labelled at the XhoI site.

Methods. F-MEL cells (clone 745) were grown in DMEM supplemented with 10% fetal calf serum (FCS), 100 U ml penicillin, 100 µg ml tomycin and 2 mM glutamine (Gibco). Transfections were performed by electroporation as described previously 31,32 in 1 ml of phosphate-buffered saline containing $1-2\times10^7$ cells ml $^{-1}$, 20 μg of linearized SV₂myc-dhfr and 2 μg of linearized pSV₂neo DNA. Immediately after electroporation, cells were kept on ice for 10 min and then replated in a series of 6-well dishes in fresh DMEM containing dialysed FCS. Two days later, the antibiotic G418 (Gibco) was added to a final concentration of 1 mg ml 1. After 2 weeks, G418-resistant clones were replated in fresh medium containing 0.25 µM MTX (Lederle) plus dialysed FCS. Surviving cells from each well were cloned by limiting dilution in 96-well microtitre dishes. In this way, we insured that each clone originated from an independent transfection event. MTX-resistant clones were expanded with continuous growth in 0.25 uM MTX. Clone 8, 15 and 21 cells were each derived from single-cell isolates of 745 cells stably transfected with pSV2myc-dhfr and pSV2neo. For S₁ nuclease studies, clones were grown for 3-5 days in the absence of MIX. DMSO was added for the times indicated and total cellular RNAs were extracted by the guanidine hydrochloride method³³. Aliquots (10 µg) of each RNA were hybridized with an end-labelled 940-nucleotide Ndel-Xhol ragment derived from pSV₂myc-dhfr $(c)^{34}$. This probe was labelled with polynucleotide kinase and $(\gamma^{-32}P]ATP$ (Amersham) to a specific activity of $\sim 10^7$ d.p.m. μg^{-1} . Hybridization reactions contained 10^5 d.p.m. of probe and $10 \mu g$ of RNA in a total volume of $10 \mu l$ of hybridization solution (80%). formamide, 300 mM NaCl, 40 mM PIPES pH 6.4, 1 mM EDTA). Reactions were placed at 85 °C for 5 min followed by a 16-h incubation at 51 °C, then treated with 300 U of S₁ nuclease (Sigma) at 37 °C for 1 h, precipitated with isopropanol and subjected to analysis on a 1.8% agarose gel.

transfected with a derivative of the plasmid shown in Fig. 1 in which myc sequences were not included or were reversed. Control F-MEL cells demonstrated 85-95% benzidine positivity after 5 days of induction whereas pSV₂myc-dhfr clones showed 10-50% staining.

Transfected clones also failed to accumulate β^{major} -globin messenger RNA as determined by Northern blot analysis of cellular RNAs (not shown). Furthermore, unlike control F-MEL cells, all three transfected clones continued to proliferate after they had been incubated for 7 days in medium containing 1.5% DMSO (not shown). We conclude from these studies that the perturbations of myc expression seen in these clones are associated with the preservation of features normally associated with the uncommitted, non-terminally differentiated state.

The inability of clone 21 cells to differentiate as well as clones 8 and 15 might have been related to levels of exogenous c-myc transcripts. Indeed, we found that these levels are two to three-fold lower in clone 21 cells than in the other clones (not shown). To address this aspect more directly, we grew cells from clone 21 in increasing concentrations of MTX. At each stage, cells were tested for their ability to differentiate in response to DMSO. RNAs were also extracted and the ratios of exogenous to

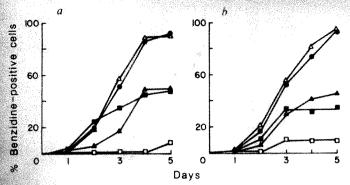

Fig. 3 Benzidine staining of F-MEL clones in response to dimethyl sulphoxide (DMSO) (a) or hypoxanthine (Hyp) (b). Equivalent numbers of cells from each of the indicated clones were cultured in the presence of 1.5% DMSO or 5 mM Hyp. At the times indicated, aliquots of cells were removed and stained with benzidine as described previously⁵. Clones 8 (**m**), 15 (**m**) and 21 (A) were each derived from single-cell clones of F-MEL clones which had been transfected with pSV₂myc-dhfr. Clone 101 (△) was derived from a transfection with the above plasmid minus the mouse c-myc sequences. Clone 745 cells () were the non-transfected parental line used for all transfection studies. Each point represents the average of three to five independent experiments.

endogenous transcripts examined. As shown in Fig. 4, benzidine staining of clone 21 cells was progressively inhibited as the concentration of MTX was raised. Exogenous c-myc transcript levels were also increased, indicating an amplification of plasmid sequences. These observations demonstrated that, at least in the case examined, progressive refractoriness to DMSO induction could be correlated with levels of exogenous mye transcripts.

The highly conserved nature of cellular oncogenes suggests that they are intimately associated with growth and/or differentiation processes. Indirect evidence in support of this comes from studies of both fresh and cultured tumour cells where aberrancies such as c-onc gene amplification, rearrangement and overexpression have been reported⁶⁻¹¹. Changes in the levels of transcripts of otherwise normal c-onc genes have been shown to accompany the normal differentiation and mitotic process both in vitro and in vivo 12-15

c-myc is a short-lived nuclear protein possessing DNAbinding properties 16 and is structurally related to the adenovirus E1A gene product which acts to trans-activate other viral genes. Indeed, c-myc itself can enhance transcription of a chimaeric gene containing the 5'-flanking region of the Drosophila hsp70 heat shock protein gene¹⁸. Together with the findings of c-myc transcript modulation during differentiation^{3,6}, these attributes make the c-myc gene product an ideal candidate to control developmental events, presumably by positively or negatively influencing the transcription of other cellular genes 19. This in turn might exert effects on proliferation since, in the case of F-MEL cells, proliferation and terminal differentiation have been shown to be intimately related²⁰.

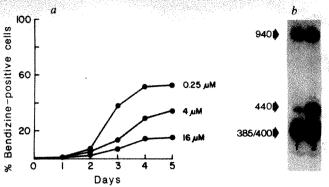

Fig. 4 The degree of F-MEL differentiation is related to the level of exogenous c-myc expression. Clone 21 cells were initially grown in 0.25 µM MTX. To amplify pSV2myc-dhfr sequences, MTX concentrations were increased fourfold for 14-day intervals. At the end of the incubation period, MTX was removed for 3-5 days to allow for recovery of viable cells. Cells were then induced with 1.5% DMSO to monitor benzidine staining (a) or were subjected to the next round of MTX selection. b, After growth in the indicated concentrations of MTX, cellular RNAs were extracted and the levels of exogenous and endogenous c-myc transcripts were determined as described for Fig. 2. The concentrations of MTX in which clone 21 cells were grown was either 0.25 µM (lane 1) or 16 µM

The aberrant expression of several c-onc genes can stimulate or inhibit differentiation in several in vitro systems²¹⁻²³. We are currently investigating the role of other c-onc genes in the differentiation of F-MEL cells. A more difficult problem will be that of the possible role of Friend virus complex genes in complementing the action of c-myc in this system.

c-myc transcripts originating from the SV40 promoter were less responsive to inducing agents than were endogenous c-myc transcripts. This is not surprising because the exogenous c-myc sequences are under the control of a foreign promoter, and the c-mye transcription unit has been substantially altered so as to contain a modification of the 5'-untranslated region and to lack first intron sequences. Both regions have been implicated in contributing to the considerable instability of normal myc mRNA²⁴. We also note that even high-level overexpression of the exogenous c-myc sequences did not affect the levels of endogenous transcripts. This result is consistent with previous observations regarding c-myc overexpression in NIH/3T3 and F-MEL cells^{25,26}.

After submission of this manuscript, Coppola and Cole reported findings similar to ours²⁶, in addition to demonstrating that some of the events leading to commitment have already occurred in c-mvc-transfected cells.

Vibrational CD of biopolymers

from T.A. Keiderling

Circular dichroism measurements in the infrared provide new insight into polypeptide structure and promise more detailed analyses of protein secondary structure.

CIRCULAR dichroism (CD), the differential absorption (ΔA) of left- and rightcircularly polarized light, has become a fundamental tool in the analysis of solution-phase protein and nucleic acid secondary structure. The method, however, has several limitations. Ordinarily studied in the ultraviolet (UV), electronic CD can access only a few excited states of the typical organic molecule. And frequently these transitions, largely dominated by π -excitations of aromatics and carbonyls, give featureless, overlapping spectral bands whose CD tends to interfere.

On the other hand, the vibrational transitions observed in the infrared (IR) region of the spectrum are typically much better resolved and more straightforward to assign and interpret than electronic transitions. Extensive spectroscopic studies have demonstrated that some aspects of vibrational spectra are characteristic of expected biomolecular structures. But sensitivity to molecular conformation is marginal.

Coupling IR and CD

Vibrational circular dichroism (VCD) combines the details of IR data with the conformational sensitivity and two-signed clarity of CD. Thus, the variety of possible spectral transitions increases dramatically, and such transitions can originate in any bond of the molecule. The great potential of VCD lies in its ability to probe discrete structural components of a molecule, vielding spectra that are unique and very strongly influenced by conformation. Thus VCD studies complement and extend the structural insights provided by the wealth of CD and vibrational spectroscopy data already available.

VCD spectra are measured on an infrared spectrometer (conventional or FTIR) that has been modified to produce and detect modulated circularly polarized light'. A wire grid polarizer creates linearly polarized light, which is subsequently oscillated between left and right circularity by means of a CaF, or ZnSe photoelastic modulator. If the sample is optically active, its VCD will in turn modulate the intensity of the incident light beam at the modulator frequency. Fast, highsensitivity IR detectors, such as Hg(Cd)-Te or InSb, are necessary to detect the modulated intensity. The signal is extracted with lock-in amplifiers and computer signal averaging.

With this apparatus, we routinely achieve a sensitivity of $\Delta A/A$ about [0]

and a range to about 900 cm. However, extension to approximately 600 cm⁻¹ and $\Delta A/A$ of 5×10^{-6} is possible. While these capabilities for the VCD of small molecules have been available for some time. only in the last two years have applications to biopolymers developed234. Part of this lag can be attributed to the difficulty of studying aqueous biological systems in the infrared. For such studies, VCD must be obtained on very thin, concentrated, deuterium-exchanged samples in D₂O held between two CaF, windows separated by a Teflon spacer. Even then, only the amide I band (C=O stretch) can be studied with present instrumentation. In non-aqueous environments, we can also study amide A (NH stretch) and II (CNH deformation) bands^{2,3,4}

Biopolymer applications

Figure 1 shows the amide I VCD and absorption spectra for three basic structural types of poly-t-lysine: random coil (rc), anti-parallel B-sheet and right-handed α -helix. Both the α -helical and rc amide I bands exhibit VCD couplets at about 1.650 cm 1, but they are of opposite sense. The β -sheet form has two negative VCD bands correlating to two absorption maxima near 1,620 and 1,680 cm

In comparison to near-UV CD findings. the re VCD results have a surprisingly large magnitude and are quite similar to the amide I VCD of left-handed α-helix previously reported14. This data has recently been interpreted as added evidence for substantial local order in the otherwise random coil". The re amide I VCD also resembles that of the poly-t-proline extended helix, which indicates the type of local structure present.

Poly-1-tyrosine in dimethylsulphoxide

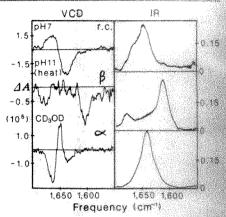

Fig. 1. Poly-t-lysine VCD and absorption spectra in the amide I region at pH 7.3 (random coil), pH 11.5 after heating (antiparalle) p sheet) and in a 96-to-4 ratio of CD OD to D.O. (right-handed α-helix). ΔA in units of 10

gives similar re spectra . Here the amide A band can be used to distinguish the respectrum from that of a left-handed or helix. Whereas interference from aros matic side chains makes electronic CD inconclusive as to secondary structure, the resolution afforded by vibrational spectra makes such analysis possible

The VCD data set for poly-t-lysine is analogous to that used initially for characterizing protein secondary structure in electronic CD. While our present data base is insufficient to make a significant impact upon such characterizations, we have obtained globular protein VCD that reflects the qualitative patterns shown in Fig. 1. For example, the amide I VCD of myoglobin and α-chymotrypsin at neutral pH demonstrate this qualitative resemblance (Fig. 2). The predominantly α-helical myoglobin clearly shows a triple-peaked VCD of the same sign pat-

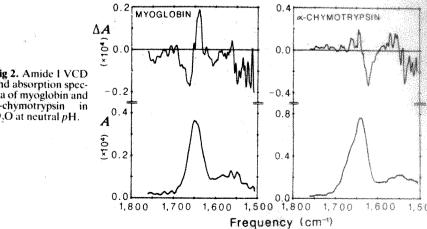

Fig 2. Amide I VCD and absorption spectra of myoglobin and α-chymotrypsin D.O at neutral pH.

tern, though of smaller magnitude, as the α-helical spectrum in Fig. 1. The αchymotrypsin, having a high β -sheet component, has a negative band at about 1,630 cm⁻¹ that parallels the high pH poly-L-lysine results. This qualitative success suggests a role for VCD in protein stereochemical studies if improved signal-tonoise ratios and VCD for other amide bands can be obtained.

But VCD's ultimate utility in protein secondary structure analysis depends in part on its sensitivity to polymer length and end effects, which has yet to be determined. In this regard, we have made studies of β -sheet-forming^{8,9} and 3_{in} helical forming oligopeptides. In particular, for the latter studies, we measured the VCD of the amide A, I and II bands of aminoisobutyric acid oligopeptides as a function of length to determine when the characteristic 3₁₀-helical VCD developed. For all three bands the characteristic magnitudes of $\Delta A/A$ are fully developed at the hexamer, which corresponds to almost two turns (three H-bonds) of an ideal 3₁₀helix. In fact the spectra evidence the same qualitative VCD as early as the tetramer, which can only form a single turn. Such results imply a dominance of relatively local interactions in VCD that is not seen in electronic CD. Thus from vibrational CD, a new level of structural insight may evolve.

Biological VCD applications are likely to focus next on the simultaneous empirical analysis of vacuum UV, near-UV and IR CD data for a series of proteins. 12 Developments with FTIR-based spectrometers should also permit better signal averaging and improved resolution.1 Finally, polarized interferometers or new modulator designs should bring the VCD of lower energy modes within range, disclosing folded biopolymer structure in even greater detail.

ACS in Anaheim

Next week over 200 exhibitors at the American Chemical Society's West Coast meeting will be ushering in autumn with labware, instrumentation and schemes for automation.

An infrared detector built specifically for capillary gas chromatography will put in an appearance at Hewlett-Packard's stand (Reader Service No. 100). The HP 5965A system, which starts at \$47,000 (US), consists of a detection module and an HP IRD ChemStation that can combine data from both GC/FTIR and GC/MS for compound identifications. The ChemStation can also integrate library search results and rank probable internal diameters based on hit quality and common matches. Hewlett-Packard, showing in booths 141 through 147 (odd) at ACS, says the IR detector takes up less than 8 inches of bench space. The company thinks its dedicated instrument will have a heightened sensitivity for capillary GC eluents, allowing, for example, detection of 5 ng isobutyl methacrylate at a signal-to-noise ratio of 20 to 1.

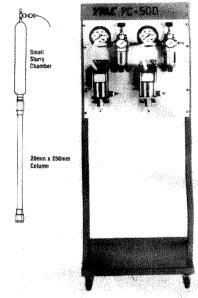

Combining non-metallic components with a novel detector array, Dionex has developed an HPLC system aimed at life sciences applications (Reader Service No. 101). The Series 4000i BioLC package has a quaternary pump that, Dionex says, can accommodate the "entire range" of HPLC techniques, including hydrophobic

The 4000i can store up to 10 programs.

interaction and ion pairing. The metalfree pump provides pressures up to 4.000 p.s.i. and flow rates from 100 µl per minute to 10 ml per min. The 4000i detectors can spot even non-chromophoric organic and inorganic ions at sub-p.p.m. levels, according to Dionex, with a pulsed amperometric detector and suppressors to reduce background and increase sensitivity. The whole assemblage will be on display in booth 717.

For chromatographers who prefer to pack their own columns, YMC Inc has two compact slurry packing systems that, the company says, can be 10 to 15 per cent more efficient than dry or tap packing methods (Reader Service No. 102). The PC-50D uses two air-actuated pressure amplifier pumps, which generate solvent flows up to 290 ml per min at pressures up

YMC packs two cohimns simultaneously

to 6,000 p.s.i., to pack LC columns with internal diameters from 4.6 mm to 20 mm. The larger PC-100D is capable of packing columns with internal diameters from 4.6 mm to 100 mm, with a larger pump to deliver solvent at 1.25 I per min at pressures up to 9,000 p.s.i. and a smaller one with the same specifications as those used in the PC-50D. YMC, at booth 705 in Anaheim, will have more information on its systems, which sell for \$3,200 (US) for the PC-50D and \$7.800 (US) for the PC-100D.

Automation links

Radiometer will have its new TitraLab wet chemistry analysis system at booth 305 in Anaheim (Reader Service No. 103). The company's programmable system automates titration procedures for both single and batch samples, switching automatically between multiple reagents, electrodes and titration procedures. Communicating via a CRT screen. TitraLab displays the titration curve during analysis and offers on-screen guidance with a HELP key. Its memory stores up to 60 user-defined methods. Radiometer's design features several different configurations for different applications to supplement the standard video titrator, triburette station and sample handler.

Software to boost the analytical prowess of Perkin-Elmer's model 7700 computer is now available for a variety of applications (Reader Service No. 104). The company claims it has written over one million lines of code to build a software selection that

spans all of its analytical instrumentation. The Perkin-Elmer Solvent Optimization System, for example, creates a multicoloured triangular graph representing the resolution of different solvent combinations. The company sells its menudriven software for prices ranging from \$400 (US) to \$3,000 (US), or in some cases as part of the hardware packages. PerkinElmer will be in a string of booths between 115 and 220 by the telephones in the Anaheim convention centre.

Three instrument couplers for laboratories undergoing automation are the subject of a new brochure from Beckman (Reader Service No. 105). Two of Beckman's Digimetry couplers, the MK5-4CV and the MK6, convert analogue signal outputs from chromatographs into digital format. Of the two, Beckman says, the

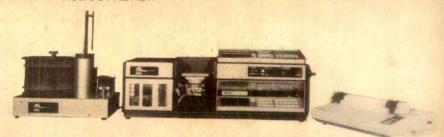

Beckman expands upon Diginetry couplers. MK5-4CV is more accurate and has onboard circuitry to validate the operational performance of each interface. The third Digimetry model, the MK5S, can collect data from as many as eight instruments with RS-232 output ports at a time. In Anaheim, Beckman will be at booths 335 through 339 (odd) to distribute further information.

Thermoanalytical determinations can now benefit from computer-aided in-

Mettler's menu-driven GraphWare system.

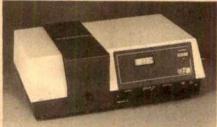

From halfway around the world, ARL's atomic absorption spectrometer has arrived

sights, owing to new software from Mettler (Reader Service No. 106). With TA70 GraphWare, up to four thermoanalytical curves can be depicted simultaneously, either superimposed or segregated each in its own window. Mettler designed the package for use with its TA3000 thermal analysis system and an IBM PC. The company, at booth 602 in the convention hall, will have more to say about TA70 GraphWare.

Scanning the spectrum

A joint effort that spanned an ocean produced the 902 atomic absorption spectrometer from Applied Research Laboratories (Reader Service No. 107). Australiabased GBC Scientific Equipment, in conjunction with ARL, engineered an AA system that is guaranteed to precision of 0.5 per cent RSD on 5 p.p.m. of Cu with an absorbance of 0.7. ARL/GBC also claims that the 902's background correction system makes the instrument "the fastest system optimized for graphite furnace signals." The AA spectrometer can be found at booth 519 at ACS. A complete doublebeam system with built-in data handling, software and a printer costs about \$17,000 (US).

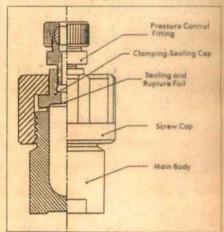

A British-made single beam spectrophotometer has just arrived on the market

AlphaSpec: filling a gap in the UK market? following an agreement between Camspec and EDT Research (Reader Service No. 108). The AlphaSpec range, priced between £1,500 and £2,530 (UK), is EDT's attempt to fill the gap Camspec identified for a low-cost single-beam instrument on the British market. Five AlphaSpec models are presently available, with visual or UV/vis ranges and digital or analogue readouts. EDT signed an original equipment manufacturer agreement with Camspec early this month for the AlphaSpec line, which will be distributed by the EDT group company Courtcloud, Courtcloud dealers and EDT itself.

Recombinant Mouse-Interferon-8

This is purified from E, coli carrying mouse IFN- β gene of mouse L-cell, using affinity chromatographies described by

S. Matsuda, et al. (to be published in J. Interferon Res).

Purity: higher than 99% by SDS-PAGE.

Blue-Cotton (Mutagen Adsorbent)

This is able to adsorb mutagens containing quite low concentration in aqueous solutions, especially those having more than three fused aromatics.

The adsorbed mutagens are easilly eluted by ammonia-methanol solution.
Blue-cotton is applied to Urine

Blue-cotton is applied to Urine, Feces, Foods, River Water, etc.

logue that outlines its latest laboratory equipment (Reader Service No. 109). Large volume high pressure autoclaves. Teflon-encased stainless-steel stir shafts. flexible corrugated tubing up to 150 feet long and pressure digestion heating blocks are just a few of the areas that incorporate PTFE, FEP, PFA and other fluorocarbon resins. Berghof will be showing its equipment at booth 428 in Anaheim.

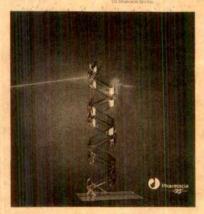

The Bioanalyzer brochure from Provesta details the theory and practice of its enzyme-electrode instrument (Reader Service No. 110). The Bioanalyzer,

A typical standard curve for the Bioanalyzer. according to Provesta, can determine the concentration of specific biochemicals or organic chemicals in complex mixtures at levels between 10 and 10 M. Using an oxygen electrode tipped with an oxidase in a gel matrix, the instrument works by measuring the decrease in oxygen at the electrode when the oxidase catalyses a reaction between oxygen and the biochemical being analysed. Information on Wednesday's Bioanalyzer workshop will be on hand at Provesta's ACS booth 726.

Pharmacia's catalogue reviews the company's recent arrivals for the molecular biologist (Reader Service No. 111). What isn't on exhibit at the biotech group's ACS booth 304 will surely be listed among the catalogue's pages. It describes many of the products Pharmacia has advanced during

Molecular **Biologicals**

Pharmacia tells all in its new catalogue.

the past year, including its DNA/RNA modifying enzymes, prokaryotic and eukaryotic vectors. DNA synthesizer and linkers for protein engineering.

For the life scientist

Right near the convention hall entrance. Orion Research in booths 702 and 704 will be touting the EA 940 pH/ISE meter with its unusual ability for expansion (Reader Service No. 112). Orion says the meter alone can be programmed to measure ions for which electrode and direct calibration procedures do not exist, or to measure samples with unknown concentrations and different sample types without calibration. But by adding the company's 960 autochemistry module, the meter can also be upgraded to a system capable of performing analyses ranging from endpoint titrations to incremental techniques. The

Three keys control most EA940 functions.

EA940 sells for \$1,995 in the United States.

Ohaus will debut its high-capacity toploading balance at ACS in booths 735 and

New heights in weights for Ohaus balances. 739 (Reader Service No. 113). The Galaxy 8000 weighs up to 8,000 g and reads to 0.1g; its taring range is also 0 to 8,000 g. The G8000's 7 × 9-inch weighing pan reflects its high capacity function. Ohaus also equipped its unit for RS-232 bidirectional data output and sample weight display in grams, pounds, troy or avoirdupois ounces, carats or pennyweights. Taring and calibration, says Ohaus, are accomplished with the touch of a button. The G8000 lists at \$1,150 (US).

These notes are compiled by Karen Wright from information provided by the manufacturers. To obtain further details about these products, use the reader service card bound inside the journal. Prices auoted are sometimes nominal and apply only within the country indicated.

CONVENIENT-INFORMATIVE-TIMELY-PROVOCATIVE

FOUR DYNAMITE REASONS WHY YOU SHOULD SUBSCRIBE TO BIO/TECHNOLOGY NOW . . .

You'll save time. Because you don't have time to read every journal in the field, BIO/TECHNOLOGY is written and edited to give you all the information you need in ONE convenient source. BIO/TECH-NOLOGY is the only journal to give you news. Features. Original research. Product evaluations. Industrial applications. Job openings. Book and product reviews. And more. If it's important to your work, you'll find it between the covers of BIO/TECHNOLOGY.

You'll learn new ways to improve your on-the-job skills and run a more successful operation. Each month BIO/TECH-NOLOGY gives you the scoop on invaluable start-up information...the latest instrumentation...marketing breakthroughs...funding sources...new technologies... patents and licences...profiles on how others are avoiding the pitfalls and reaping the rewards. In fact, just one practical tip from BIO/-TECHNOLOGY can be worth many times the cost of your subscription.

You'll be up-to-date on all major industry developments. With correspondents all over the world, BIO/TECHNOLOGY delivers the inside story on who's doing what, where You'll get the latest word on changing government regulations and tax law, and how they affect your work.

Plus you'll read original research papers by bench scientists, engineers, and biologists that will help keep you in the forefront of every new discovery worth knowing about.

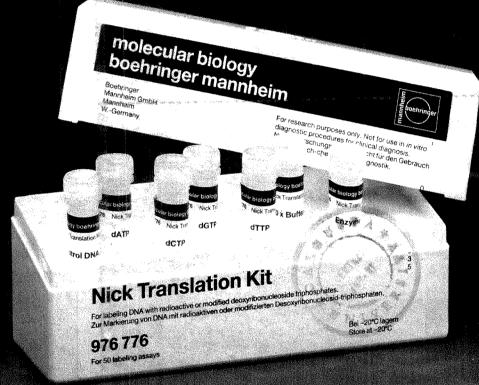

You'll get new ideas you can put to use immediately.BIO/TECHNOLOGY lets you rub elbows with eminent scientists, tour new facilities and learn how new processes work in every field from genetic engineering to molecular biology. Each month, BIO/TECHNOLOGY helps spark ideas for your own research, for new industrial applications and for getting along in the increasingly competitive financial arena.

If you're not already subscribing to BIO/TECHNOLOGY, don't delay the moment any longer - return the coupon below and we will send you twelve issues. You risk nothing. If for any reason BIO/TECHNOLOGY doesn't live up to your highest expectations, just let us know and you'll receive a full refund on all unmailed copies. Remember too, that your subscription may be tax deductible.

TO START RECEIVING YOUR SUBSCRIPTION, FILL OUT THE COUPON BELOW AND RETURN WITH PAYMENT TO:
